The *prevalence* method described in the paper by Peto et al.^[12] is routinely used by statisticians in testing for positive trends in prevalence rates of incidental tumors. The method can be described briefly as follows.

The prevalence method focuses on the age-specific tumor prevalence rates to correct for intercurrent mortality differences among treatment groups in the test for positive trends or differences in incidental tumors. The experimental period is partitioned into a set of intervals plus interim (if any) and terminal sacrifices. The incidental tumors are then stratified by those intervals of survival times. The selection of the partitions of the experimental period does not matter very much as long as the intervals "are not so short that the prevalence of incidental tumors in the autopsies they contain is not stable, nor yet so large that the real prevalence in the first

half of one interval could differ markedly from the real prevalence in the second half.^{12]}

In each time interval, for each group, the observed and the expected numbers of animals with a particular tumor type found in necropsies are compared. The expected number is calculated under the null hypothesis that there is no dose-related trend. Finally, the differences between the observed and the expected numbers of animals found with the tumor type after their deaths are combined across all time intervals to yield an overall test statistic using the method described in the paper of Mantel and Haenszel.^[22]

The following derivation of the Peto prevalence test statistic uses the notations in Table 3. Let the experimental period be partitioned into the following m intervals, $I_1, I_2, \dots, I_m$. As mentioned before, interim (if any) and terminal sacrifices should be treated as separate intervals. The number of autopsied animals expected to have the particular incidental tumor in group i and interval k , under the null hypothesis that there is no treatment effect, is:

$$E_{ik} = O_{.k} P_{ik}$$

The variance-covariance of $(O_{ik} - E_{ik})$ and $(O_{jk} - E_{jk})$ is:

$$V_{ijk} = P_{ik} (\delta_{ij} - P_{jk})$$

where

$$\delta_{ij} = \begin{cases} 1 & \text{if } I = j \\ 0 & \text{otherwise.} \end{cases}$$

Define

$$O_i = \sum_k O_{ik}$$

$$E_i = \sum_k E_{ik}$$

$$V_{ij} = \sum_k V_{ijk}$$

The test statistic T for the positive trend in the incidental tumor is defined as:

$$T = \sum_i D_i (O_i - E_i)$$

with estimated variance $V(T) = \sum_i \sum_j D_i D_j V_{ij}$ where D_i is the dose level of the i th group. Under the null hypothesis of equal prevalence rates among the treatment groups, the statistic $Z = \frac{T}{[V(T)]^{1/2}}$ is approximately distributed as a standard normal.

As mentioned earlier, to use the prevalence method, the experimental period should be partitioned into a set of intervals plus interim (if any) and terminal sacrifices. The following partitions (in weeks) are used most often in 2-year studies: (i) 0–50, 51–80, 80–104, interim sacrifice (if any), and terminal sacrifice; (ii) 0–52, 53–78, 79–92, 93–104, interim sacrifice (if any), and terminal sacrifice (proposed by National Toxicology Program [NTP]); and (iii) partition determined by the “ad hoc runs” procedure described in Peto et al.^[12]

The data of liver hepatocellular adenoma of male mice from a carcinogenicity experiment of a new drug are used as examples to explain the prevalence method for testing the positive trend in tumor rates of an incidental tumor.

Table 3 Notations Used in the Derivation of Peto Prevalence Test Statistics

	Group	0	1	...	i	...	r	
Interval	Dose	D_0	D_1	...	D_i	...	D_r	Sum
I_1	R_1	O_{01}	O_{11}	...	O_{i1}	...	O_{r1}	$O_{.1}$
		P_{01}	P_{11}	...	P_{i1}	...	P_{r1}	$P_{.1}$
I_2	R_2	O_{02}	O_{12}	...	O_{i2}	...	O_{r2}	$O_{.2}$
		P_{02}	P_{12}	...	P_{i2}	...	P_{r2}	$P_{.2}$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
I_k	R_k	O_{0k}	O_{1k}	...	O_{ik}	...	O_{rk}	$O_{.k}$
		P_{0k}	P_{1k}	...	P_{ik}	...	P_{rk}	$P_{.k}$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
I_m	R_m	O_{0m}	O_{1m}	...	O_{im}	...	O_{rm}	$O_{.m}$
		P_{0m}	P_{1m}	...	P_{im}	...	P_{rm}	$P_{.m}$

R_k = number of animals that have not died of the tumor type of interest but come to autopsy in timeinterval k .

P_{ik} = proportion of R_k in group i .

O_{ik} = observed number of autopsied animals in group i and interval k found to have the incidental tumor type.

$O_{.k} = \sum_i O_{ik}$.

Table 4 Data on Liver Hepatocellular Adenoma of Male Mice

Time interval (weeks)	Group											
	Control			Low			Medium			High		
	<i>T</i>	<i>N</i>	%	<i>T</i>	<i>N</i>	%	<i>T</i>	<i>N</i>	%	<i>T</i>	<i>N</i>	%
0–50	0	6	0	0	2	0	0	2	0	0	4	0
51–80	1	26	4	1	18	6	3	17	18	1	13	8
81–106	4	37	11	2	14	14	2	14	14	7	19	37
Terminal sacrifice	2	31	6	5	16	31	3	17	18	4	14	29
Total	7	100	7	8	50	16	8	50	16	12	50	24

T = number of necropsies with the particular tumor.

N = number of necropsies during a time interval.

% = percentage of necropsies with the particular tumor.

There were four treatment groups in the mouse experiment. The control group had 100 animals; the three treated groups had 50 animals each. The dose levels used were 0, 10, 20, and 40 mg/kg/day for the control, low, medium, and high groups, respectively. The study lasted for 106 weeks. In this example, the study period was partitioned into four intervals: 0–50, 51–80, 81–106, and terminal sacrifice. The numbers of animals died and necropsied and the numbers of necropsied animals with liver hepatocellular adenoma by treatment group in each interval are included in Table 4.

The observed rates and the expected rates of the tumor type calculated under the null hypothesis that there is no trend (or drug-induced increase) are shown in Table 5. The expected tumor rates in each interval were calculated in the following way. First, the tumor rate for the interval using data of all treatment groups in the interval was estimated. For example, the estimated tumor rate for the interval 51–80 weeks is $6/74 = 0.0811$. Second, the expected rates for individual groups in the interval were calculated by multiplying the numbers of necropsies by the estimated

tumor rate. For the interval 50–81 weeks, the expected tumor rates for the control, low, medium, and high groups are $26 \times 6/74 = 2.11$, $18 \times 6/74 = 1.46$, $17 \times 6/74 = 1.38$, and $13 \times 6/74 = 1.05$, respectively.

The values of the test statistic *T* and its variance *V(T)* for the data of the five intervals calculated by the formulas listed earlier are included in Table 6. It is noted that the first interval, 0–50 weeks, did not contribute to the overall test result because none of the 14 animals that died during the time interval developed liver hepatocellular adenoma. The overall result shows a statistically significant positive trend in tumor rates for this tumor (with one-sided *p*-value = 0.002). Also, as mentioned earlier, this method uses normal approximation in the tests for positive trend or difference in tumor prevalence rates. The accuracy of the normal approximation depends on the number of tumor occurrences in each group in each interval, the number of intervals used in the partitioning, and the mortality patterns. The approximation may not be stable and reliable when the numbers of tumor occurrences across treatment groups are small. In this situation, an exact permutation trend test based on an extension of the hypergeometric distribution (to be discussed in the section “Exact Tests”) is used to test for the positive trend in tumor prevalence rates.

Table 5 Observed and Expected Tumor Rates for Liver Hepatocellular Adenoma of Male Mice

Time interval (weeks)	Observed and expected rates	Group			
		Control	Low	Medium	High
0–50	Observed	0	0	0	0
	Expected	0	0	0	0
51–80	Observed	1	1	3	1
	Expected	2.11	1.46	1.38	1.05
81–106	Observed	4	2	2	7
	Expected	6.61	2.50	2.50	3.39
Terminal sacrifice	Observed	2	5	3	4
	Expected	5.56	2.87	3.05	2.51
Total	Observed	7	8	8	12
	Expected	14.28	6.83	6.93	6.95

Expected tumor rates were calculated under the null hypothesis that there is no trend.

Table 6 Test Statistics, Their Variances, *z* Values, and *p*-value of Peto Prevalence Analysis of Incidental Tumors for Liver Hepatocellular Adenoma of Male Mice

Time interval (weeks)	<i>T</i> statistic, <i>T</i>	Variance of <i>T</i> stat, <i>V(T)</i>	<i>z</i> = <i>T</i> / [<i>V(T)</i>] ^{0.5}	<i>p</i> value
0–50	–	–	–	–
51–80	25.6756	1116.583	0.7683	0.2211
81–106	129.2857	3091.314	2.3253	0.0100
Terminal sacrifice	79.7435	2445.855	1.6124	0.0534
Overall total	234.7048	6653.752	2.8773	0.0020

The *z* and *p*-value columns do not add up to the totals. The *z* and *p*-values for the overall total row were calculated based on the *T* and *V(T)* for the row.

Tests of Data of Fatal Tumors

The death-rate method described in Peto et al.^[12] should be utilized to test for the positive trend or difference in tumors observed in a fatal context.

The notations of “Tests of Data of Incidental Tumors,” with some modifications, will be used in this section to derive the test statistic of the death-rate method. Now let $t_1 < t_2 < \dots < t_m$ be the time points when one or more animals died of the fatal tumor of interest. These time points replace the intervals used in the prevalence method. The notations in Table 3 are redefined as follows:

- R_k = number of animals of all groups just before t_k .
- P_{ik} = proportion of R_k in group i (same as in prevalence method).
- O_{ik} = observed number of animals in group i dying of the fatal tumor of interest at time t_k .
- $O_{.k} = \sum_i O_{ik}$.

As in the prevalence method, the test statistic T for the positive trend in the fatal tumor is defined as: $T = \sum_i D_i(O_i - E_i)$ with estimated variance $V(T) = \sum_i \sum_j D_i D_j V_{ij}$ where D_i , O_i , E_i , and V_{ij} are defined as in “Tests of Data of Incidental Tumors.”

Under the null hypothesis of equal tumor rates across the treatment groups, the statistic $Z = \frac{T}{[V(T)]^{1/2}}$ is distributed approximately as standard normal.

Tests of Data of Tumors Observed in Both Incidental and Fatal Contexts

When a tumor is observed in a fatal context for some animals and is also observed in an incidental context for other animals in the experiment, data of the incidental tumor part should be analyzed by the prevalence method, and data of the fatal tumor part should be analyzed by the death-rate method using all animals as at risk of death with the tumor. Results from the different methods can then be combined to yield an overall result. The combined overall result can be obtained simply by adding together either the separate observed frequencies, the expected frequencies, and the variances, or the separate T statistics and their variances.^[12]

Tests of Data of Mortality-Independent Tumors

Tumors observed in a mortality-independent context, such as skin tumors and mammary gland tumors, that are visible and/or can be detected by palpation in living animals should be analyzed using the onset-rate method. The onset-rate method for mortality-independent tumors and the death-rate method for fatal tumors are essentially the same in principle except that the endpoint in the onset-rate method is the occurrence of such a tumor (e.g., skin tumor

reaching some prespecified size) rather than the time or cause of the animal's death.

In the onset-rate method, all those animals that, although still alive, have developed the particular mortality-independent tumor and, hence, are no longer at risk for such a tumor are excluded from the calculation of the numbers of animals at risk. The R_k , P_{ik} , and O_{ik} described in “Tests of Data of Fatal Tumors” are now redefined as follows for the onset-rate method:

- R_k = number of animals alive and free of the mortality-independent tumor of interest in all groups just before t_k .
- P_{ik} = proportion of R_k in group i (same as in death-rate method).
- O_{ik} = observed number of animals in group i found to have developed the mortality-independent tumor of interest at time t_k .

The test statistic T and its estimated variance $V(T)$ are the same as those defined in the death-rate method.

Exact Tests

As mentioned in previous sections, the prevalence method, the death-rate method, and the onset-rate method use normal approximation in the test for the positive trend in tumor incidence rates. Mortality patterns, the number of intervals used in the partitioning of the study period, and the numbers and patterns of tumor occurrence in each individual interval have effects on the accuracy of the normal approximation. It is also well known that the approximation results may not be stable and reliable and that they tend to underestimate the exact p values when the total numbers of tumor occurrence across treatment groups are small.^[23] In this situation, the exact permutation trend test should be used to test for the positive trend.^[6] The exact permutation trend test is a generalization of the Fisher's exact test to a sequence of $2 \times (r + 1)$ tables. The exact permutation trend test procedure described next is for tumors observed in an incidental context. However, the positive trends in incidence rates of tumors observed in a fatal or in a mortality-independent context can be tested in a similar way. In those cases, the number of $2 \times (r + 1)$ tables will be equal to the number of time points when one or more animals died of a particular fatal tumor or when one or more animals developed a particular mortality-independent tumor. Fairweather et al.^[24] contains a discussion on the limitations of applying exact methods to fatal tumors.

The exact method is derived by conditioning on the row and column marginal totals of each of the $2 \times (r + 1)$ tables formed from the partitioned data set of Table 3. Consider the k th interval, I_k , (in Table 3) and rewrite it as in Table 7. Let the column totals C_{0k} , C_{1k} , ..., C_{rk} and the row totals $O_{.k}$ and $A_{.k}$ be fixed. Define $P_{ik} = C_{ik}/R_k$. Then the quantities $E_{ik} = O_{.k}P_{ik}$, $V_{ijk} = P_{ik}(\delta_{ij} - P_{jk})$, E_i , and $V(T)$ (defined in

Table 7 Data in the k th Time Interval, I_k , are Written as a $2(r+1)$ Table

	Group	0	1	...	i	...	r	
	Dose	D_0	D_1	...	D_i	...	D_r	Total
Number with tumor		O_{0k}	O_{1k}	...	O_{ik}	...	O_{rk}	$O_{.k}$
Number without tumor		A_{0k}	A_{1k}	...	A_{ik}	...	A_{rk}	$A_{.k}$
Total		C_{0k}	C_{1k}	...	C_{ik}	...	C_{rk}	R_k

“Evaluation of Validity of Designs of Negative Studies”) are all known constants.

Now let y be the observed value of $Y = \sum D_i O_i$, where $O_i = \sum_k O_{ik}$, the total number of tumor-bearing animals with the tumor of interest in treatment group i . Then (under conditioning on the column and row marginal totals in each table) the observed significance level

$$\begin{aligned}
 p \text{ value} &= P\left[\sum D_i O_i \geq y\right] = P\left(\sum_i D_i \sum_k O_{ik} \geq y\right) \\
 &= P\left(\sum_k \sum_i D_i O_{ik} \geq y\right) \\
 &= P\left(\sum_k Y_k \geq \sum_i y_k\right) = P(Y \geq y)
 \end{aligned}$$

where $Y = \sum Y_k = \sum_k \sum_i D_i O_{ik}$, and $y = \sum y_k$, the observed value of Y . The p value $P(Y \geq y)$ is computed from the exact permutational distribution of Y . Given the observed row and column marginal totals in a $2 \times (r+1)$ table, all possible tables having the same marginal totals can be generated. Let S_k ($k = 1, 2, \dots, K$) be the set of all such tables generated from the k th observed table. From a set of K tables taking one from each S_k and assuming independence between the K tables, the foregoing expression for the p value can now be written as $p \text{ value} = \sum [P(Y_1 = y_1) \dots P(Y_k = y_k)]$ where $y_k = \sum_i D_i O_{ik}$ ($k = 1, 2, \dots, K$), the sum is over all sets of K tables such that $y_1 + y_2 + \dots + y_K \geq y$, the observed value of Y , and $P(Y_k = y_k)$ is the conditional probability given the marginal totals in the k th table, i.e.,

$$P(Y_k = y_k) = \frac{\left(\begin{matrix} C_{0k} \\ O_{0k} \end{matrix} \right) \left(\begin{matrix} C_{1k} \\ O_{1k} \end{matrix} \right) \dots \left(\begin{matrix} C_{rk} \\ O_{rk} \end{matrix} \right)}{\left(\begin{matrix} R_k \\ O_{.k} \end{matrix} \right)}$$

The following example illustrates how the probabilities are computed in the exact permutation trend test described earlier. Consider an experiment with three treatment groups (control, low, and high) with dose levels $D_0 = 0$, $D_1 = 1$, and $D_2 = 2$, respectively. Suppose the study period is partitioned into the intervals 0–50, 51–80, and 81–104 weeks and the terminal sacrifice week. Consider a tumor type (classified as incidental) with data as in Table 8. As all the observed tumor counts (i.e., O s) in the first two time intervals are zero, the data for these intervals will not contribute anything to the test statistic and these intervals may be ignored. The observed subtables formed from the last two intervals are given in Table 9.

Now generate all possible tables from observed subtable 1. As the marginal totals are fixed, these tables may be generated by distributing the total tumor frequency $O_{.1} (= 2)$ among the three treatment groups. Thus, each table will correspond to a configuration of this distribution of $O_{.1}$. The configurations, the values of Y_1 , and the $P(Y_1 = y_1)$ are shown in Table 10.

Table 8 Hypothetical Tumor Data for Exact Permutation Trend Test

Time interval		Dose level			Total
		0	1	2	
0–50	O	0	0	0	0
	C	1	3	3	7
51–80	O	0	0	0	0
	C	4	5	7	16
81–104	O	0	0	2	2
	C	10	12	15	37
Terminal sacrifice	O	0	1	0	1
	C	35	30	25	90

O = observed tumor count; C = number of animals necropsied.

Table 9 Observed Subtables from the Hypothetical Tumor Data of Table 8

Observed subtable 1					Observed subtable 2				
Dose	0	1	2	Total	Dose	0	1	2	Total
O	0	0	2	$2 = O_{.1}$	O	0	1	0	$1 = O_{.2}$
A	10	12	12	$35 = A_{.1}$	A	35	29	25	$89 = A_{.2}$
C	10	12	15	$37 = R_1$	C	35	30	25	$90 = R_2$

Table 10 All Possible Configurations of O_1 and the Corresponding Hypergeometric Probabilities

Configuration	y_1	$P(Y_1 = y_1)$
0,0,2	4	0.15766
0,2,0	2	0.09910
2,0,0	0	0.06757
0,1,1	3	0.27027
1,0,1	2	0.22523
1,1,0	1	0.18018

Table 11 All Possible Configurations of O_2 and the Corresponding Hypergeometric Probabilities

Configurations	y_2	$P(Y_2 = y_2)$
0,0,1	2	0.27778
0,1,0	1	0.33333
1,0,0	0	0.38889

To illustrate the computation of y_1 and $P(Y_1 = y_1)$, consider the last row. Here

$$y_1 = D_0 \times 1 + D_1 \times 1 + D_2 \times 0 \\ = 0 \times 1 + 1 \times 1 + 2 \times 0 = 1$$

and

$$P(Y_1 = 1) = \frac{\binom{10}{1} \binom{12}{1} \binom{15}{0}}{\binom{37}{2}} = \frac{10 \times 12 \times 2}{37 \times 36} \\ = 0.18018$$

The configurations and probabilities obtained from observed subtable 2 are given in Table 11. Note that the first configuration (0,0,2) in Table 10 corresponds to the observed subtable 1 with a value of $y_1 = (0 \times 0) + (1 \times 0) + (2 \times 2) = 4$ and a probability of 0.15766, and the second configuration (0,1,0) in Table 11 corresponds to the observed subtable 2 with a value of $y_2 = (0 \times 0) + (1 \times 1) + (0 \times 0) = 1$ and a probability of 0.33333. Thus, the observed value of $y = y_1 + y_2 = 4 + 1 = 5$. Now the exact p value (right-tailed) is calculated as follows:

$$P(Y = Y_1 + Y_2 \geq 5) = P(Y_1 = 4, Y_2 = 1) \\ + P(Y_1 = 4, Y_2 = 2) \\ + P(Y_1 = 3, Y_2 = 2) \\ = 0.15766 \times 0.33333 + 0.15766 \\ \times 0.27778 + 0.27027 \\ \times 0.27778 \\ = 0.17142$$

For the purpose of comparison, it may be noted that the normal approximated p -value for the data set in our example is 0.0927.

TESTS FOR TREND AND DIFFERENCE IN TUMOR INCIDENCE IN CHRONIC STUDIES USING POLY-K TESTS

As mentioned previously, in the analysis of tumor data, it is essential to identify and adjust for possible differences in intercurrent mortality among treatment groups in order to eliminate or reduce biases caused by these differences. However, most tumors, except those that can be detected by palpation and visual inspection, such as skin tumors, are discovered only at the time of the animal's death. The exact tumor onset times are censored and, therefore, are unidentifiable and unobservable. "Without direct observations of the tumor onset times, the desired survival adjustment usually is accomplished by making assumptions concerning tumor lethality, cause of death, multiple sacrifices, or parametric models."^[3]

There is considerable discussion in the literature on statistical tests for positive trend in tumor incidence rate based on those assumptions and models. Some of those proposed statistical tests are not practical because they are based on either uncommon designs with serial sacrifices or mathematical assumptions that are not realistic and/or cannot be verified. The widely used prevalence method, the death-rate method, and the onset-rate methods for analyzing incidental, fatal, and mortality-independent tumors, respectively, described in the previous sections, rely on the information on tumor lethality and cause of death. That is, the choice of a survival-adjusted method to analyze tumor data depends on the role that a tumor plays in causing the animal's death.^[8,12]

There are situations in which sponsors do not include the tumor lethality and cause-of-death information in their statistical analyses and in their submitted electronic data sets. Under those situations, statistical reviewers in regulatory agencies either treat all tumors as incidental or, if provided, follow the cause-of-death information determined by reviewing pharmacologists and toxicologists in the agencies. There are consequences in misclassifying tumors and misusing survival-adjusted statistical tests. The use of the prevalence method will reject the null hypothesis of no positive trend less frequently than it should as the lethality of a tumor increases.^[3,12] This will increase the probability of failing to detect true carcinogens.

The poly-3 and poly-6 (in general, poly- k) tests^[3,25-28] have been proposed for testing linear trends in tumor rates. These tests are basically modifications of the survival-unadjusted Cochran-Armitage test^[29-31] for linear trend in tumor rate. If the entire study period is considered as one interval, the data of a particular tumor will be in the form

Table 12 Data Using the Entire Study Period as an Interval

Group	0	1	...	i	...	r	
Dose	D_0	D_1	...	D_i	...	D_r	Total
Number with tumor	O_0	O_1	...	O_i	...	O_r	O
Number without tumor	A_0	A_1	...	A_i	...	A_r	A
Total	C_0	C_1	...	C_i	...	C_r	R

of Table 12. The notations in Table 12 to be used to explain these tests are the same as those in Table 7 except that the k th interval is now the entire study period. The second subscript, k (for the k th interval), was dropped from the notations.

The Cochran-Armitage test statistic for linear trend^[30] in tumor rate is defined as:

$$\chi_{CA}^2 = \frac{R\{R\sum O_i D_i - O\sum C_i D_i\}^2}{O(R-O)\{R\sum C_i D_i^2 - (\sum C_i D_i)^2\}} \text{ or } \frac{\{\sum D_i(O_i - E_i)\}^2}{\sum E_i D_i^2 - (\sum E_i D_i)^2 / O}$$

where $O = \sum O_i$, $A = \sum A_i$, $R = \sum C_i$, and $E_i = OC_i/R$. The test statistic χ_{CA}^2 is distributed approximately as χ^2 on one degree of freedom. The Cochran-Armitage linear trend test is based on a binomial assumption that all animals in the same treatment group have the same risk of developing the tumor over the duration of the study. However, as mentioned previously, the animal's risk of developing the tumor increases as study time increases. The assumption is no longer valid if some animals die earlier than others. It has been shown that as long as the mortality patterns are similar across treatment groups, the Cochran-Armitage test is still valid although it might be slightly less efficient than a survival-adjusted test.^[3] However, if the mortality patterns are different across treatment groups, the Cochran-Armitage test can give very misleading results.

The poly-3 test adjusts the differences in mortality among treatment groups by modifying the number of animals at risk in the denominators in the calculations of overall tumor rates in the Cochran-Armitage test to reflect "less-than-whole-animal contributions for decreased survival."^[25] The modification is made by defining a new number of animals at risk for each treatment group. The number of animals at risk for the i th treatment group C_i^* is defined as $C_i^* = \sum w_{ij}$ where w_{ij} is the weight for the j th animal in the i th treatment group, and the sum is over all animals in the group.

Bailer and Portier^[25] proposed applying the weight w_{ij} as follows:

$$w_{ij} = \begin{cases} 1 & \text{to animals dying with the tumor} \\ \left(\frac{t_{ij}}{t_{\text{sacr}}}\right)^3 & \text{to animals dying without the tumor.} \end{cases}$$

where t_{ij} is the time of death of the j th animal in the i th treatment group, and t_{sacr} is the time of terminal sacrifice.

The power of 3 used in the weighting is from the observation that tumor incidence can be modeled as a polynomial of order 3. Similarly, the poly-6 test (or the general poly- k test) assigns the weight, $w_{ij} = (t_{ij}/t_{\text{sacr}})^6$ [or $w_{ij} = (t_{ij}/t_{\text{sacr}})^k$] to animals dying without the tumor when the tumor incidence is close to a polynomial of order 6 (or order k).

The class of poly- k tests is carried out by replacing the C_i s by the new numbers of animals at risk C_i^* s in the calculation of the foregoing Cochran-Armitage test statistic.

Bieler and Williams^[26] showed that the poly-3 trend test is anticonservative when tumor incidence rates are low and treatment toxicity is high. They proposed a test called the *ratio trend test* that is another modification to the Cochran-Armitage linear trend test. The ratio trend test employs the adjusted quantal response rates calculated in Bailer and Portier^[25] and the delta method^[32] in the estimation of the variance of the adjusted quantal response rates, $p_i^* = O_i/C_i^*$. The ratio trend test treats both the numerator and the denominator of the adjusted quantal response rate as being subject to random variation.

The computational formula for Bieler-Williams ratio trend (modified C-A) test statistic is given as follows:

$$\chi_{BW}^2 = \frac{\sum m_i p_i^* D_i - (\sum m_i D_i)(\sum m_i p_i^*) / \sum m_i}{\left\{c \left[\sum m_i D_i^2 - (\sum m_i D_i)^2 / \sum m_i \right]\right\}^{1/2}}$$

where

- $c = \sum \sum (r_{ij} - r_i)2/[R - (r + 1)]$.
- $m_i = C_i^*/C_i$.
- $r_{ij} = y_{ij} - p^* w_{ij}$.
- y_{ij} = tumor response indicator (0 = absent at death, 1 = present at death) for the j th animal in the i th group.

It is noted that the notation c in the above formulas is not the same as C_i , the number of animals in group i

(see Table 12), and the notation r for the number of treatment $r + 1$ is not the same as r_{ij} and r_i defined above.

Bieler and Williams^[26] further showed that for tumors with low background rates, the ratio trend test yielded actual type I errors close to the nominal levels used and was observed to be less sensitive than the poly-3 trend test to misspecification of the shape of tumor incidence function and the magnitude of treatment toxicity.

The classes of poly- k tests and the ratio trend test adjust for differences in survival, do not need the information on cause of death, and require only a (the terminal) sacrifice. They are also relative robust to (not affected greatly by) tumor lethality. Results of simulation studies^[3,25] show that these tests performed very well under many conditions simulated. Those tests should be used to replace the asymptotic tests that depend on the information on tumor lethality and on cause of death when the information is not available. As in the case of the Peto tests, it is well known that the approximation results of poly- k tests may also not be stable and reliable and that they tend to underestimate the exact p -values when the total numbers of tumor occurrence across treatment groups are small. Exact versions of the above the poly- k tests should be used for testing data from tumor types with small numbers of tumor-bearing animals. However, because these tests use risk sets based on all animals in each treatment group, the computations involved in the exact tests will be extensive.

Statistical reviewers of carcinogenicity studies in the Center for Drug Evaluation and Research (CDER) of Food and Drug Administration (FDA) have recently decided to move toward the replacement of the Peto tests by the poly- k tests. The following are the reasons for FDA statistical reviewers to change the statistical tests in their reviews.

As mentioned previously, the Peto tests require the information of cause-of-death of individual tumors on individual animals. The information may not be available, or even is available but may not be accurate and reliable since it is difficult for pathologists to determine objectively if a tumor causes the death of an animal. Misclassifications of the cause-of-death information of tumor types can produce misleading results as also mentioned previously.

Most of the time, the Peto tests use the partitions of study duration into sets of fixed time intervals for all tumor types for the practical purpose in data analysis. However, this practice in the Peto tests becomes problematic when some treatment groups were terminated early. In those situations, the numbers of treatment groups in individual time intervals will be different, and there is no clear way to combine the results of individual time intervals to obtain the overall results of the tests.

For incidental tumor data analysis, the data in a time interval containing 0/0s, that is, no death, even just for a single group, were excluded in the analysis. This can result in excluding a big amount of data. Although this problem can be overcome by using different partitions of the study duration, such as using the ad hoc runs procedure

described in the Peto et al. paper, for different incidental tumor types to avoid time intervals containing 0/0s, it may be impractical in terms of time and efforts needed to complete the statistical review of carcinogenicity studies of a new drug submission.

In some widely used commercially developed computer programs, there is a problem in the exact permutation test for trend in incidence in a tumor that is fatal for some animals and is incidental for the other animals. When a tumor types is observed under fatal and incidental contexts of observation, the permutation of the fatal tumor rates will affect the denominators of the incidental tumor rates because a death is changed from fatal to incidental in one treatment group has to be compensated by the change of a death from incidental to fatal in the treatment group in which the original fatal tumor bearing animal is moved to. Table 13 contains an example illustrates the above problem.

One permutation of the fatal incidences moving the fatal tumor-bearing animal from the medium group to the control group will result in the changes in the incidental incidences shown in Table 14.

However, those computer systems just use the fatal and incidental incidences in Table 15 to do the computation without adjusting the changes in the denominators of the incidental incidences. Using frequency tables without proper changes of denominators of the incidental incidence rates will produce invalid final overall results of exact tests.

Since the poly- k tests do not require the cause-of-death information, the above problem of the exact test for a tumor

Table 13 Example Data of Original Fatal and Incidental Incidences in a Given Time Interval of a Given Tumor Type

	Control	Low	Medium	High
Fatal	0/45	0/42	1/42	0/42
Incidental	3/10	0/12	2/12	1/15

Table 14 One Permutation of the Fatal Incidences Resulting in Changes in the Numerators and Denominators of the Incidental Incidences

	Control	Low	Medium	High
Fatal	1/45	0/42	0/42	0/42
Incidental	3/9	0/12	2/13	1/15

Table 15 One Permutation of the Fatal Incidences without Changing the Denominators of the Incidental Incidences

	Control	Low	Medium	High
Fatal	1/45	0/42	0/42	0/42
Incidental	3/10	0/12	2/12	1/15

that is observed under both fatal and incidental contexts of observation in the Peto tests won't be a problem in the exact version of the poly-*k* tests.

ANALYSIS OF DATA FROM TRANSGENIC MOUSE CARCINOGENICITY STUDIES

The high cost (between \$2 and \$3 million) and long time (a minimum of three years) needed to conduct a standard long-term in-vivo carcinogenicity study and the increased insight into the mechanisms of carcinogenicity due to the advances made in molecular biology have led to alternative in-vivo approaches to the assessment of carcinogenicity. People also argue that that genetically altered mice are better animal surrogates for human cancer because they carry some specifically activated oncogenes that are known to function in both human and animal cancers. The International Conference on Harmonization (ICH) has developed a document, accepted by the United States and other countries, titled—"Guidance on Testing for Carcinogenicity of Pharmaceuticals" Federal Register, vol. 63, 8983–8986, 1998) (ICH, 1998).^[2] The guidance outlines experimental approaches to the evaluation of carcinogenic potential that may obviate the necessity for the routine use of two long-term rodent carcinogenicity studies, allowing sponsors either to continue to conduct two long-term rodent carcinogenicity studies or to use the alternative approach of conducting one long-term rodent carcinogenicity study together with a short- or medium-term rodent test. The short- or medium-term rodent test systems include studies such as initiation-promotion in rodents, transgenic rodents, or newborn rodents that provide rapid observation of carcinogenic endpoints in vivo.

Studies using transgenic mice have become the most important alternative to carcinogenicity testing among the short- or medium-term rodent test systems recommended in the ICH guideline. Many new studies of known carcinogens and non-carcinogens from previous two-year bioassays using transgenic rodents have been carried out by the National Toxicological Program (NTP) and by the International Life Science Institute (ILSI) to evaluate the specificity and sensitivity of the alternative test system.^[33] Different strains of transgenic mice (models) have been proposed and used in the alternative system of testing carcinogenicity of pharmaceutical and environmental chemical compounds. We also have seen and reviewed carcinogenicity studies of pharmaceuticals using transgenic mice submitted by drug companies. The following are the main strains (models) having been proposed and used in the studies mentioned above: (i) p53+/- transgenic mice (with knockout of one of the two alleles of the tumor suppression gene p53), (ii) Tg.AC transgenic mice (with genetically initiated skin to induce epidermal papillomas in response to dermal or oral exposure to chemical agents and act as a reporter phenotype of the activities of the tested

chemicals), (iii) Tg.rasH2 transgenic mice (with five or six copies of the stable human c-Ha-ras gene—they were first developed and patented in Japan), and (iv) XPA-/- repair deficient mice (developed in Europe).

The standard study protocol described below has been used in the above studies.

1. Study duration: 26 weeks
2. A positive control group in addition to the regular three or four treatment groups (negative control, low, medium, and high)
3. 15–30 animals per sex/treatment group.
4. Tissues/organs of p53+/-, Tg.rasH2, and XPA-/- repair deficient mice died or terminally sacrificed are microscopically examined for neoplastic and non-neoplastic lesions.
5. In studies using Tg.AC transgenic mice, only data (both incidence rates and numbers of papillomas observed over time) of tumor type of skin papillomas are collected and tested for drug effects.

In general, the exact and asymptotic tests for trend and difference in tumor incidence with or without requirement of cause-of-death information for the traditional two-year study can be applied to carcinogenicity studies using p53+/-, Tg.rasH2, and XPA-/- transgenic mice since the endpoints in these two types of study are the same.

Because of the major differences in designs used—that is, use of 15–30 animals per sex/group and only one or two treated groups and a small number of tumor types developed in animals in the new type of study—the decision rules used in the two-year studies may have to be modified in order to maintain a desirable level of overall false positive rate. Also, because only 15–30 animals per sex/group are used, the power of the trend and pairwise comparison tests should be evaluated.

Methods for analyzing the numbers of skin papilloma in studies using Tg.AC transgenic mice are somewhat different from those for studies using the above models. Incidence rates of skin papilloma (proportions of animals with the tumor) can be analyzed by the same exact or asymptotic tests for trend and difference in incidence with or without requirement of cause-of-death information in regular two-year studies. Individual weekly counts of skin papilloma data can be analyzed by Mann-Whitney and Jonckheere tests for pairwise difference and positive trend, respectively.

However, the more recently developed method by Dunson et al.^[34] that uses data of all time points in one analysis has been using by the statistical reviewers in the FDA's Center for Drug Evaluation and Research (CDER).

The Dunson model for analyzing the number of papillomas is expressed as follows:

$$\begin{aligned} \mu_{ij} &= E(Y_{ij} | M_{ij}, b_i, t_i, d_i) = \exp\{\beta_1 + (b_i + \gamma_1)t_i d_i\} \quad \text{if } M_{ij} = 0 \\ \text{or} \quad \mu_{ij} &= E(Y_{ij} | M_{ij}, b_i, t_i, d_i) = \exp(\beta_2 + \gamma_2 d_i) \quad \text{if } M_{ij} \neq 0 \end{aligned}$$

where

μ_{ij} is the Poisson mean of the number of papillomas on the back of mouse i observed at week j .

$Y_{ij} = M_{i,j+1} - M_{ij}$ is the increase in the maximum papilloma burden for mouse i between week $j-1$ and j . It is assumed that Y_{ij} has a Poisson distribution with mean μ_{ij} .

M_{ij} = maximum ($Z_{i1}, \dots, Z_{i,j-1}$) is the maximum papilloma burden observed for mouse i prior to week j .

Z_{ij} is the number of detectable papillomas on the back of mouse i at week j .

b_i is a mouse specific susceptibility variable. It is assumed to have a normal distribution with mean zero and variance σ^2 .

$t_j = j/T$, and T is the duration of the study.

d_i is the dose level on the log scale for mouse i .

β_1 and β_2 are the intercept parameters related to the rate of appearance of spontaneous papillomas.

γ_1 and γ_2 are the slope parameters associated with exposure.

The first expression of the model relates to tumor onset. If γ_1 is zero, then the dosing of the drug does not affect the probability of an animal developing its initial papilloma during the study. Alternatively, a large estimated value of γ_1 implies that the exposed animals develop papillomas more rapidly, or equivalently, a higher proportion of the exposed animals developed papillomas during the study. The second expression of the model relates to tumor multiplicity. If $\gamma_2 = 0$, then the dosing of the drug does not affect the probability of developing additional papillomas during the study, once an initial papilloma has occurred. The mouse specific variable accounts for possible heterogeneity in response among the animals.

ANALYSIS OF DATA FROM STUDIES USING DUAL CONTROL GROUPS

There are two categories of studies with dual control groups. The first category (Category A) includes studies using an untreated control group and a vehicle control group. The second category (Category B) includes studies that use two identical control groups.^[35,36]

The main reasons for using an untreated control and a vehicle control in a study in Category A are to check if the vehicle substance has effects, such as spontaneous tumor incidence and pattern, body weight, and food consumption (in dietary studies) on the test animals, and to make sure that the control animals are subjected to the same method and the route of exposure (e.g., by gavage or by injection) experienced by the treated animals so that all animals will be under equal physiological responses and stress (i.e., to isolate the treatment effect from other possible effects).^[6,37]

There are arguments for and against using two identical controls in a study in Category B. The arguments for using

this type of design are to employ the results from the two identical controls as a quality control mechanism for identifying unsuspected biases in the study^[6] and to evaluate the biological significance of increases in tumor incidence in the treated groups (i.e., true increases vs. noises). However, as described later, difficulties are encountered in statistical analysis of data from a study in this category. Also, there is a concern about the possible existence of extrabinomial within-study variability between the two identical groups that will result in an inflation of false-positive rates. These difficulties and concerns form the basis for the arguments against the use of designs with two identical controls.

Statisticians and pharmacologists/toxicologists should work together to decide which of the two control groups is appropriate for the analysis of data from a study in Category A. There are situations in which only analyses of data of the vehicle control and the treated groups are meaningful. There are other situations in which three sets of analysis are performed: control 1 versus treated groups, control 2 versus treated groups, and control 1 plus control 2 versus treated groups. As the concerns about the possible effects of the vehicle substance on the test animals are the reasons for using the vehicle control in addition to the untreated control, it is also of interest to compare the mortality, the tumor rates, the body weight, and the food consumption (in dietary studies) between the two control groups.

Depending on mortality and tumor rates, data from dual control groups may or may not be combined for statistical analysis of data from studies in Category B. If comparisons of the dual controls show no major differences in mortality and tumor rate, then the data of the two controls are combined to form a single control group in subsequent analyses.^[26] If the data show evidences of major differences in mortality or tumor incidence between the identical controls, then three tests for each tumor/organ combination are carried out: control 1 versus treated groups, control 2 versus treated groups, and control 1 plus control 2 versus treated groups.

There is the question of how to interpret the results of a study in Category B in the second case. Two approaches to the question exist. The first approach is that a trend or a difference in tumor rate is considered as significant only if it is significant at the levels of significance described in "Adjustment for the Effect of Multiple Tests (Control over False-Positive Error)" in all the three tests. The second approach is that the trend or the difference is considered significant as long as any one of the three tests shows a significant result. The first approach may be very conservative in the sense that the null hypothesis will be rejected much less often than it should be. On the other hand, the second approach may result in a high false-positive error.

There is no information about appropriate levels of significance for the tests of these two approaches in order to maintain the 10% overall false-positive rate or about the

exact consequences of the two approaches in the second practice of dealing with dual controls with differences in tumor incidence or mortality. Unless all three tests yield consistent results—that is, all are significant or all are not significant from the statistical perspective—the most prudent way of interpreting the test results under this circumstance may be either to regard the study as providing equivocal evidence of carcinogenicity or to consider the study as inadequate for meaningful evaluation.^[38] Alternatively, from the biological perspective, the dual-control data may be viewed as equivalent to contemporary historical data. In such a biological evaluation of the data, consideration of other appropriate historical control data is essential.

Recently, the statisticians and pharmacologists/toxicologists reviewing carcinogenicity studies of pharmaceuticals in the FDA's Center for Drug Evaluation and Research (CDER) have reached an agreement that data of the dual identical control groups should always be pooled in the statistical analysis of the tumor data. However, the incidence rates of tumors of the two dual identical control groups should be tabulated separately with those of the treated groups.

INTERPRETATION OF RESULTS OF STATISTICAL TESTS

Interpreting the results of carcinogenicity experiments is a complex process, and there are risks of both false-negative and false-positive results. The relatively small number of animals used and the low tumor incidence rates can cause a carcinogenic drug not to be detected (i.e., a false-negative error is committed). Because of the large number of comparisons involved (usually two species, two sexes, 20–30 tissues examined), there is also a great potential for finding statistically significant positive trends or differences in some tumor types that are due to chance alone (i.e., a false-positive error is committed). Therefore, it is important that an overall evaluation of the carcinogenic potential of a drug takes into account the multiplicity of statistical significance of positive trends and differences and that it makes use of historical information and other information related to biological relevance (e.g., positive findings at the same site in the other sex and/or in the other species, and evidence of increased preneoplastic lesions at the target organs/tissues).

Adjustment for the Effect of Multiple Tests (Control over False-Positive Error)

It is well known that trend tests are more powerful (i.e., with higher probability) than pairwise comparisons for detecting a true carcinogen. Also, it is difficult to justify the use of data from only the control and the high-dose groups in a study having four or five treatment groups. Therefore,

it is believed that tests for trend, either Peto tests or poly-*k* tests, instead of pairwise comparison tests between control and high-dose groups, should be the primary tests in the evaluation of drug-related increases in tumor rate.

Statistical and nonstatistical procedures have been proposed for controlling the overall false-positive rate. Surveys of some of those procedures can be found in Lin and Ali,^[11] Rahman and Lin^[15] and Fairweather et al.^[24] Here only the statistical decision rules for controlling the overall false-positive rates associated with trend tests and pairwise comparisons in interpreting the final results of carcinogenicity studies are discussed.

In the past, statisticians used the statistical decision rule developed by Haseman^[39] in tests for significance of trends in tumor incidence. The decision rule was originally developed for pairwise comparison tests in tumor incidence between the control and the high-dose groups and was derived from results of carcinogenicity studies conducted in the NTP. The decision rule tests the significance differences in tumor incidence between the control and the dose groups at the 0.05 level for rare tumors and at the 0.01 level for common tumors. A tumor type with a background rate of 1% or less is classified as rare by Haseman and as common otherwise. Haseman's original study and a second study using more recent data with higher tumor rates show that the use of this decision rule in the control-high pairwise comparison tests would result in an overall false-positive rate between 7% and 8% and between 10% and 11%, respectively.^[39,40]

There has been some concern about the possibility of an excessive overall false-positive error when the Haseman decision rule is applied to the trend tests because data from all treatment groups are used in the tests. Unpublished results from recent studies within FDA show that this concern is valid. Based on those studies, the overall false-positive error associated with trend tests with the use of the Haseman decision rule just mentioned is about twice as large as that associated with control-high pairwise comparison tests.

Based on recent studies using real historical control data of CD-1 mice and CD rats from Charles River Laboratory and on simulation studies conducted by the author and in collaboration with the NTP, a new statistical decision rule for tests for positive trend in tumor incidence has been developed. The new decision rule tests, again either Peto tests or poly-*k* tests, for the positive trend in incidence rates in rare and common tumors at the 0.025 and 0.005 levels of significance, respectively. The new decision rule achieves an overall false-positive rate of around 10% in a standard two-species and two-sex study.^[28,41] The 10% overall false-positive rate is seen by regulatory statisticians as appropriate in a new-drug regulatory setting.

Statistical literature concentrates on the methodology of tests for positive trend in tumor rate for the two reasons already mentioned. However, there are situations

in which pairwise comparisons between control and individual treated groups may be more appropriate than trend tests based on the following pharmacological consideration: Trend tests assume that a response of the biological system (carcinogenic effect) is related to doses or systemic exposure weights or ranks. The assumption may be true for simple, direct-acting carcinogens in studies not complicated by excessive toxicity. However, there are many cases in which the response to a drug metabolite is mediated through receptor (or enzyme) effects that may be saturated even at the low dose, or is compounded by dose-related toxicity, or is complicated by a myriad of other nonlinear forms. Under those situations, the original decision rule by Haseman^[39] should be used in interpreting the results of the pairwise comparison tests. It is suggested that both trend tests and pairwise comparison tests be conducted.

As mentioned previously, the ICH made provision for drug sponsors either to continue to conduct two long-term rodent carcinogenicity studies or to use the alternative approach of conducting only one long-term rodent carcinogenicity study and a short- or medium-term transgenic rodent test system to evaluate the carcinogenic potential of their drug products. The current strategy agreed to by the regulatory agencies and the associations of pharmaceutical manufacturers of the ICH is to encourage drug sponsors to use the alternative approach to test the carcinogenicity of their products. Unpublished results from a separate study by the author using historical control data of CD rats and CD mice^[42,43] showed that the use of significance levels 0.05 and 0.01 in tests for positive trend in incidence rates of rare tumors and common tumors, respectively, will result in an overall false-positive rate of around 10% in a study in which only one 2-year rodent bioassay is conducted. The decision rule for testing differences in incidence rates between the control and individual treated groups in a study in which only one 2-year rodent bioassay is conducted is under development and is not available at the moment.

The decision rules for testing positive trend or differences between control and individual treated groups in incidence rates for standard studies using two species and two sexes, and studies following the ICH guideline and using only one 2-year rodent bioassay, are summarized in Table 16.

Use of Historical Control Data

The concurrent control group is always the one that is most appropriate and important in testing drug-related increases in tumor rates in a carcinogenicity experiment.^[44] However, if used appropriately, historical control data can be very valuable in the final interpretation of the study results. Due to the large study-to-study variations caused by differences in nomenclature, laboratory, time period, and pathologists, it is extremely important that the historical control data chosen should be comparable with the current study. Appropriate historical control data is useful in classifying and assessing the significance of rare tumors. Because statistically significant findings in rare tumors are less likely to be due to false-positive error, they provide strong evidence of carcinogenic potential. For this reason, rare tumors can be tested with less stringent statistical decision rules. However, as mentioned previously, an overall evaluation of the carcinogenic potential of a drug should take into account the multiplicity of statistical significance of positive trends and differences and make use of historical information and other information related to biological relevance. In cases of marginally significant trends, historical control data can be used to help investigators evaluate if those findings are biologically significant. If the tumor rates in the treated groups in the experiment are within the normal ranges of the historical control data, then the marginally significant findings can be discounted. Historical control data can also be used as a quality control mechanism for a carcinogenicity experiment by assessing the reasonableness of the spontaneous tumor rates in the concurrent control group^[44] and for evaluation of disparate findings in dual concurrent controls.

Often the informal use of historical control data in the interpretation of statistical testing results just mentioned above is not satisfactory because the normal ranges of the historical control data are too wide. There are proposed formal statistical procedures that allow the incorporation of appropriate historical control data in tests for trend in tumor rate having been proposed. Tarone,^[45] Hoel,^[46] Hoel and Yanagawa,^[47] and Tamura and Young^[48,49] proposed some empirical procedures using the beta-binomial distribution to model historical control tumor rates and to derive approximate and exact tests for trend. The results from those studies show that the incorporation of the historical control data improves the power of the tests.

Table 16 Statistical Decision Rules Aiming at Controlling Overall False-Positive Rates Associated with Tests for Positive Trend or with Control-High Pairwise Comparisons in Tumor Incidences to Around 10% in Carcinogenicity Studies of Pharmaceuticals

	Tests for positive trend	Control-high pairwise comparisons
Standard studies with two species and two sexes	Common and rare tumors are tested at 0.005 and 0.025 significance levels, respectively	Common and rare tumors are tested at 0.01 and 0.05 significance levels, respectively (by Haseman's rule)
Alternative ICH studies with one species and two sexes	Common and rare tumors are tested at 0.01 and 0.05 significance levels, respectively	Under development and not available at the moment

The greatest improvement of power is shown in the tests for rare tumors. Dempster et al.^[50] proposed a Bayesian procedure to incorporate historical control data in statistical analysis. The procedure uses the assumption that the logits of the historical control tumor rates were normally distributed.

There are some technical issues in the use of these formal statistical procedures. They work well in the situations in which historical data from a large number of studies with relatively large control groups are available for obtaining reliable estimations of the parameters of the prior distributions. The maximum likelihood estimators (MLEs) of the prior parameters were shown to be unstable, and the distributions of the MLEs were skewed to the right, i.e., with bunching above the mean and a long tail below the mean. The skewness is severe for cases in which only historical data of a few small control groups were available. The skewness of the MLEs inflates the type I error of the tests. Also, these procedures were developed to incorporate historical control data into the Cochran-Armitage test for linear trend in tumor incidence. As the Cochran-Armitage test is a survival-unadjusted procedure, these procedures cannot be applied to studies with significant differences in survival among treatment groups.

The formal procedure, discussed in Tarone^[45] and below, has been used by statistical reviewers in the FDA's Center for Drug Evaluation and Research (CDER). The formal statistical procedure works well in situations in which historical data from a large number of studies with relatively large control groups are available to provide reliable estimations of the parameters of the prior distributions. The results from this study show that the incorporation of the historical control data improves the power of the tests. The greatest improvement of power is shown in the tests of rare tumors.

Consider an experiment involving $r + 1$ groups (one control and r treated groups) of animals with increasing doses $d_0 = 0 < d_1 < \dots < d_r$. The numbers of animals in the $r + 1$ are $n_0, n_1, \dots, n_r$. The numbers of animals developed a particular tumor in those groups are $x_0, x_1, \dots, x_r$. To test for an increase in the proportions $\hat{p}_i = X_i/n_i$ with increasing dose level, Cochran and Armitage suggested the test statistic

$$\chi^2 = \left(\sum x_i d_i - \hat{p} \sum n_i d_i \right)^2 / \left\{ \hat{p} \hat{q} \left[\sum n_i d_i^2 - \left(\sum x_i d_i \right)^2 / n \right] \right\}, \quad (1)$$

where $n = \sum n_i$, $x = \sum x_i$, $\hat{p} = x/n$, and $\hat{q} = 1 - \hat{p}$. The summation is from zero to r when there are $r + 1$ treatment groups in an experiment.

The test statistic χ^2 is distributed asymptotically as a chi-square random variable with one degree of freedom.

For a given experiment, the number of animals that develop the tumor in the control group follows the binomial distribution with parameter p .

$$f(x) = f(x) = \binom{n}{x} p^x (1-p)^{n-x} \text{ for } x = 0, 1, \dots, n. \quad (2)$$

p is the true spontaneous rate of the tumor, n is the total animals in the control group, and x is the number of animals in the control group developed the tumor.

It is proposed in the paper that the following beta distribution be used to model the distribution of the spontaneous tumor rate p of the control group that varies from experiment to experiment.

$$g(p) = \{ \Gamma(\alpha + \beta) / \Gamma(\alpha) \Gamma(\beta) \} p^{\alpha-1} (1-p)^{\beta-1}, \text{ for } 0 < p < 1.$$

The mean and variance of the beta distribution are

$$E(p) = \alpha / (\alpha + \beta)$$

and

$$V(p) = (\alpha\beta) / \{ (\alpha + \beta)^2 (\alpha + \beta + 1) \}$$

The unknown parameters α and β are estimated by the method of moments, that is, by equating the population mean and variance with the sample mean and variance and solving the two equations to find the estimates of α and β , or by the maximum likelihood method.

The positive trend in tumor incidence with the incorporation of historical control data is tested by the following statistic

$$\tilde{\chi}^2 = \left(\sum x_i d_i - \tilde{p} \sum n_i d_i \right)^2 / \left\{ \tilde{p} \tilde{q} \left[\sum n_i d_i^2 - \left(\sum x_i d_i \right)^2 / \tilde{n} \right] \right\},$$

where $\tilde{n} = n + \hat{\alpha} + \hat{\beta}$, $\tilde{p} = (x + \hat{\alpha}) / \tilde{n}$, $\tilde{q} = 1 - \tilde{p}$, $n = \sum n_i$, $x = \sum x_i$, and $\hat{\alpha}$ and $\hat{\beta}$ are estimates of α and β . The summation is from zero to r when there are $r + 1$ treatment groups in an experiment.

The test statistic $\tilde{\chi}^2$ is distributed asymptotically as a chi-square random variable with one degree of freedom.

Table 17 contains the data of hepatocellular adenoma and hepatocellular adenoma+carcinoma in B6C3F1

Table 19 Comparison of Results of the Cochran-Armitage Tests on Data of Hepatocellular Adenoma, Hepatocellular Carcinoma, and Hepatocellular Adenoma and Carcinoma Combined in Female B6C3F₁ Mice with and without the Use of Historical Control Data

Tumor Type	<i>p</i> -value without the Use of Historical Control Data	<i>p</i> -value with the Use of Historical Control Data
Hepatocellular adenoma	0.0048	0.0090
Hepatocellular adenoma + Carcinoma	0.0020	0.0077

female mice in a carcinogenicity study of a new drug, and Table 18 contains the historical control data of the two tumor types from 17 studies using the same strain of animals. The statistical method of trend test incorporating historical control data described above was applied to the concurrent control data and the historical control data of the 17 previous studies. The results of the Cochran-Armitage trend tests with and without the use of the historical control data are presented in Table 19. The results in the table show that the use of the historical control data in the trend tests significantly increases the *p*-values although they are all statistically significant at 0.05 significance level.

Evaluation of Validity of Designs of Negative Studies

In negative or equivocal studies, i.e., studies for which statistical tests did not detect any statistically significant positive trend or difference in tumor rate,^[51] the statistical reviewers should perform a further evaluation of the validity of the design of the experiment to see if there were sufficient numbers of animals living long enough to get adequate exposure to the chemical and to be at risk of forming late-developing tumors and to see if the doses used were adequate to present a reasonable tumor challenge to the tested animals.

As a rule of thumb, a 50% survival rate of the 50 initial animals in any treatment group between weeks 80 and 90 of a 2-year study may be considered a sufficient number and adequate exposure. However, the percentage can be lower or higher if the number of animals used in each treatment/sex group is larger or smaller than 50, but between 20 and 30 animals should still be alive during these weeks.

The adequacy of doses selected and of the animal tumor challenge in long-term or transgenic rodent carcinogenicity experiments is evaluated by pharmacologists and toxicologists based on the previously mentioned ICH approaches as well as the results of the long-term or transgenic rodent carcinogenicity experiments. To assist the evaluation, statistical reviewers in the FDA's Center for Drug Evaluation and Research (CDER) are often asked to provide analyses of body weight and mortality differences and, occasionally, differences of other data between treated and control groups.

Carry-Forward Analysis

Naitee Ting

Pfizer Global Research and Development, New London, Connecticut, U.S.A.

Abstract

Carry-forward analysis is a useful tool in analyzing longitudinal clinical data with dropout problems. This entry addresses some of the regulatory considerations regarding the issue of carry-forward analysis, provides statistical methods, and presents a numerical example of this type of analysis.

INTRODUCTION

In clinical studies, data are often collected over time. The data collected over a period of time from subjects participating in these studies are referred to as *longitudinal* data by statisticians and biometricians. In longitudinal studies, each subject contributes multiple observations to the analysis. These observations are assumed to be correlated within a subject. It is frequently the case in clinical research that subjects drop out of a study before completion. This leads to an analytical challenge usually referred to as the *missing-data problem*. A number of references discussed the issues of missing data (e.g., Ref. [1]), and dropouts (e.g., Ref. [2]), as well as how to handle these problems (e.g., Ref. [3]).

OVERVIEW

In a report of clinical study results, it is often desirable to perform an “all randomized subjects” analysis. Implementation of this principle becomes a major challenge in data analysis when subjects drop out of the study, and no subsequent follow-up information is available. Supposing this principle is interpreted as analyzing all of those subjects who were randomized to the study, imputation techniques can be an easy way to implement it; that is, for those subjects who did not complete the study, data are inputted so that these subjects can be included in the “all randomized subjects” analysis.

One popular imputation method used in the pharmaceutical industry is to analyze the last observation carry-forward (LOCF) data. The concept of carrying observations forward can best be illustrated by an example. Suppose in a 4-week clinical study, subjects are evaluated at baseline (week 0) and at weeks 1, 2, 3, and 4 after baseline and the clinical objective is to study the drug effect at week 4. Efficacy measurements are collected at these five time points (weeks 0, 1, 2, 3, and 4). In this study, the primary comparison of treatment effect

is made by comparing changes-of-efficacy measurements from baseline to week 4. Among all subjects randomized to this study, assume that N subjects contribute the baseline measurement and at least one postbaseline measurement. After the study was completed, there were n_1 subjects who dropped out before week 2, an additional n_2 subjects who dropped out before week 3, and finally, n_3 more subjects who dropped out before week 4. The week 4 analysis would contain only $N - n_1 - n_2 - n_3 = n$ subjects, if only observed data are analyzed. In order to analyze all N subjects, data collected from the $(N - n)$ subjects who dropped out must be used. One way is to take the last observed value prior to dropout from each of these subjects and treat them as the final data (i.e., carry forward the last observation from each subject who dropped out before the week 4 evaluation).

This concept is very useful in analyzing data at a fixed time point. In this example, if the objective is to compare the subjects' responses at week 4, then LOCF has been a convenient way to include all of the N subjects. In this case, the focus is to analyze data at one or a few selected time points, instead of evaluating the response for the overall time course. It can be viewed as a type of univariate analysis, rather than the repeated-measure analysis. Under LOCF, it is assumed that the distribution of responses after some subjects have dropped out of the study is not different from the distribution of responses at the last available time point.

The section on “Regulatory Requirements” discusses some of the regulatory considerations regarding this issue. The section on “Statistical Methods” describes some statistical methods for handling carry-forward analysis. A numerical example is presented in the section “A Numerical Example.” Results are discussed in the following section (“Discussion”).

REGULATORY REQUIREMENTS

In general, regulatory guidelines do not cover carry-forward analyses specifically. These types of discussions

usually appear under the “Intention-to-treat” or other related topics. Recently, the International Conference on Harmonization (ICH) proposed a set of documents in an attempt to set global standards for drug development and approval considerations. These documents are generally referred to as the ICH Guidelines. The current version of ICH E9 Guideline^[4] discusses analysis based on “all randomized subjects” and analysis based on “per protocol subjects.” In Section 5.2 of ICH E9, this document states:

The intention-to-treat principle implies that the primary analysis should include all randomized subjects. In practice this ideal may be difficult to achieve.... [A]nalysis sets referred to as “all randomized subjects” may not, in fact, include every subject. For example, it is common practice to exclude from the all randomized set any subjects who failed to take at least one dose of trial medication or any subject without data postrandomization. No analysis is complete unless the potential biases arising from these exclusions are addressed and can be reasonably dismissed.

In practice, clinical study results are analyzed following the intention-to-treat principle. It is obvious from the quoted paragraph that the analysis of “all randomized subjects” may not be easily achieved. Therefore, the idea is to define a group of subjects as close to the “all randomized subjects” as possible, and statistical analyses are performed on this group. When this happens to the case, imputation methods are often used to obtain such a group of subjects. Carry-forward analysis is a natural application of the imputation concept.

Using the example given in the “Introduction” section, the best representative group of intention-to-treat subjects is the group of N subjects who contribute the baseline measurement and at least one postbaseline measurement. It is important to note that this group of subjects can be less than the “all randomized subjects,” because there may be subjects who were randomized to the study but did not contribute either the baseline or any postbaseline measurements, and those subjects are not included. In the analysis of changes from baseline to the week 4 response for these “intention-to-treat” subjects, carry-forward methods can be used to implement this data set.

The ICH E9 (Section 5.2) further states:

The “per protocol” set of subjects, sometimes described as the “valid cases,” the “efficacy” sample or the “evaluable subjects” sample, defines a subset of the data used in the all randomized subjects analysis and is characterized by the following criteria:

- i. the completion of a certain per-specified minimal exposure to the treatment regimen;
- ii. the availability of measurements of the primary variable(s);
- iii. the absence of any major protocol violations including the violation of entry criteria where the nature of

and reasons for these protocol violations should be defined and documented before breaking the blind.

In the previous example, the primary objective is to study the treatment effects after subjects were treated with the study medication for 4 weeks. Hence the group of per protocol subjects is the group of n subjects who completed the 4-week treatment.

ICH E9 further indicates that consistent analytical results across various sets of subjects will support clinical conclusions. In this example, if the intention-to-treat (LOCF), the per protocol subjects (week 4 completer), and other possible analyses demonstrate similar results, then the conclusion would be more robust. In case these results are inconsistent, additional analyses will be needed to investigate the differences further.

In the United States, the Food and Drug Administration (FDA) Guidelines are prepared for diseases or therapeutic areas separately. If carry-forward analysis is relevant to a specific therapeutic area, then the corresponding FDA Guideline may mention it briefly. For example, in the treatment of rheumatoid arthritis, long-term clinical studies are typically carried out, and dropouts are very common in these studies. Hence the FDA Draft Guideline for Rheumatic Diseases^[5] covers this issue. This draft states:

Methods used to handle dropouts, such as the “LOCF” and “completers” analyses, are not fully satisfactory although they have often served as the basis for determining that adequate statistical evidence of efficacy has been provided. The LOCF method generally does not preserve the size of the test.

This indicates that clinical conclusions based only on LOCF and completer analysis may not be robust, so additional analyses may also be necessary. The advantages and disadvantages of imputation methods (in particular, LOCF analysis) are discussed in “Discussion.”

STATISTICAL METHODS

Statistical methods used to analyze the carry-forward data are the same as those used to analyze the original data. For example, if the proposed analytical method is to apply analysis of variance (ANOVA) on the original data, then ANOVA can be applied to analyze the carry-forward data.

In clinical trials, response measurements are often disease specific. Some of these measurements include blood pressure (for cardiovascular diseases), forced expiration volume at 1 sec (FEV_1 , for pulmonary diseases), hemoglobin A_{1c} (HbA_{1c} , for diabetes), number of swollen joints (for rheumatoid arthritis), and brief psychiatric reading scale (BPRS, for schizophrenia) are usually treated as continuous variables in data analysis. Hence the carry-forward data from these variables are also analyzed as continuous

variables. For these data, *t*-test, ANOVA, analysis of covariance (ANCOVA), other linear models, or nonlinear models are often used to perform the statistical analysis.

In many cases, categorical data such as physician assessment (no symptom, mild, moderate, severe, and very severe), pain relief (5-point scale, 0 indicates no pain relief, 4 indicates complete pain relief), number of emetic events in a given time interval, and patient response scale (markedly deteriorated, moderately deteriorated, deteriorated, no change, improved, moderately improved, and markedly improved) are used as response variables. Hence the carry-forward data are categorical. In these cases, the methods used to analyze categorical data can also be applied to analyze the carry-forward data. Under certain circumstances, nonparametric techniques are applied for the analysis of the original data; these nonparametric methods can then be applied to analyze the carry-forward data.

There are also other ways of carrying forward observations are applied in clinical trials. Examples include carrying forward the worst case, carrying forward the best case, and carrying forward baseline. In the case of carrying forward the worst case, it is assumed that the subject's condition deteriorated after dropping out, and the worst value the subject ever experienced during the study is used as the analysis value. When the best case is carried forward, it is assumed that the subject dropped out because the subject recovered. In another situation, baseline values may be carried forward for the analysis. Carrying forward baseline requires the assumption that the treatments have no effect on responses for those subjects who dropped out. It is not a common practice to carry forward baselines. One extreme type of imputation in a study comparing a test drug against placebo is to carry forward the best values of placebo-treated subjects and the worst values for test-drug-treated subjects.

Carry-forward analysis can also be viewed as carrying forward the weighted-average responses (see, e.g., Ref. [6]), carrying forward the linear trend, or using other modeling approaches to impute data for subjects who dropped out. One simple way of carrying forward weighted-average responses is to compute the mean of all the available observations after baseline for each subject, to treat this mean as the response measurement for the subject, and then to analyze these individual means. Carry-forward linear trend can be implemented by estimating the slope for each subject first and then analyzing these slopes as subject responses. Some of these methods can be illustrated by the numerical example in the next section.

A NUMERICAL EXAMPLE

Simulated data are used to demonstrate the idea of carry-forward analysis in this numerical example. Suppose that, in a 4-week clinical trial to study subject responses to a new drug, 80 subjects were randomized to be treated with either the new drug (treatment B) or placebo (treatment A). Each subject visited the clinic five times—baseline (before the subject was dosed with the randomized study medication), 1, 2, 3, and 4 weeks after baseline. For this particular study, the primary response variable is a symptom score, possible values can be between 0 (no symptom) and 20 (worst case), inclusive. Data from some of these subjects are given in Table 1; the number of subjects at each visit by treatment group is summarized in Table 2.

In Table 1, we see that subjects 1, 4, 6, 8, 10,..., 80 were randomized to be treated with placebo (treatment A), and subjects 2, 3, 5, 7, 9,... were treated with the new drug (treatment B). For subject 1, the baseline value (BAS) was 18; that is, this subject started with a symptom score of 18 before receiving any dose of the study medication

Table 1 Simulated Data from Some of These Subjects

Treatment	Subject	BAS	W1	W2	W3	W4	LOCF	WOCF
A	1	18	16	20	16	18	18	18
B	2	13	11	13	9	10	10	10
B	3	15	17	14	11	.	11	17

.	.	.	.	.	.	.	.	.
A	80	15	13	13	14	17	17	17

Table 2 Number of Subjects at Each Visit by Treatment Group

Treatment	Baseline	Week 1	Week 2	Week 3	Week 4
A	40	40	39	32	29
B	40	40	34	32	28

(placebo, for this subject). The symptom improved slightly after the first week of treatment week 1 (W1) value was 16, and then deteriorated to 20 at week 2 (W2), and became 16 at week 3. After 4 weeks of treatment, the symptom score of this subject returned to a value of 18 (W4). In this case, the last observation carried forward (LOCF) is 18, and the worst case carried forward (WOCF) was also 18. Subject 3 visited the clinic for the first 3 weeks of treatment but did not have the week 4 evaluation. Hence the LOCF is to carry forward the last available value: 11 (LOCF = 11), but the worst case this subject experienced was 17 (from week 1), and thus the WOCF is 17. In this example, it is assumed that most subjects dropped out of the study because of lack of disease improvement. Hence carry-forward best values are not included in this example. Baselines are not carried forward here, either.

In [Table 2](#), we see that 40 subjects were randomized to each treatment group ($N = 40$ for both A and B). No subject dropped out before week 1 visit. One and six subjects dropped out after week 1 from treatments A ($n_1 = 1$) and B ($n_1 = 6$), respectively. For treatment group A, $n_2 = 7$, $n_3 = 3$, and $n = 29$. For treatment group B, $n_2 = 2$, $n_3 = 4$, and $n = 28$.

The objective of this study is to demonstrate that the new drug improves the disease symptom more than the placebo does. Before entering the study, subjects with the disease under study were randomized at baseline. After 4 weeks of treatment, the improvement can be measured using the difference in symptom score from baseline to week 4. In this example, two-sample t -tests are used to make these comparisons. [Table 3](#) illustrates these analytical results.

Note in [Table 3](#) that the BAS result is the comparison of baseline symptom scores (measured before subjects took any study medication) between treatment groups A and B.

DW4 is the comparison of differences from baseline to the week 4 visit; that is, for each subject, DW4 is obtained by subtracting the baseline score from the corresponding week 4 score. Then the DW4 values are compared between the two treatment groups. DLOCF denotes the difference from baseline to LOCF; DWOCF denotes the difference from baseline to WOCF. In these differences, a negative value indicates an improvement. The results in [Table 3](#) are part of the SAS output from the PROC TTEST based on the assumption that treatments A and B have equal variance for all four variables.

In [Table 3](#), the comparison under BAS (baseline) demonstrates that 40 subjects are randomized to each of treatment A and B ($N = 40$ for TRT = A, and $N = 40$ for TRT = B). Subjects in treatment group A have a baseline mean score of 12.775 with a standard deviation of 3.18. Subjects in treatment group B have a mean score of 11.85 with a standard deviation of 3.33. When comparing these two treatment groups, the t -test value (under the equal-variance assumption) is 1.2696 with 78 degrees of freedom (DF), and the p -value is 0.2080, indicating no significant difference between treatments A and B at baseline.

Comparisons under DW4 indicate that treatment A has 29 subjects completing the week 4 visit ($N = 29$), with a mean improvement of 0.552 units in symptom score and a standard deviation of 2.028. Treatment B has 28 subjects with a mean of 1.786 and a standard deviation of 2.079. Under the equal-variance assumption, the t -test value is 2.2683, which is significant at 0.0273 ($p < 0.05$), with 55 DF . This indicates that when the 4-week completers (subjects who completed 4 weeks of treatment) are analyzed, the new drug improves disease symptom by 1.786 units, which is significantly more than with the placebo (0.552 units).

DLOCF provides 40 subjects per treatment group because with LOCF, every subject has an improvement score to be analyzed, regardless of whether a subject dropped out or not. Mean improvement from the new drug treatment (B) is 1.65 units, which is significantly more ($p = 0.0099$, assuming equal variance) than the 0.425 units from the placebo-treated subjects. Similarly, DWOCF

Table 3 Results Obtained from t -Tests

Variable	TRT	N	Mean	Standard deviation	Standard error	T	DF	Prob T
BAS	A	40	12.77500000	3.18238340	0.50317900	1.2696	78.0	0.2080
	B	40	11.85000000	3.33243578	0.52690436			
DW4	A	29	-0.55172414	2.02812734	0.37661379	2.2683	55.0	0.0273
	B	28	-1.78571429	2.07912273	0.39291726			
DLOCF	A	40	-0.42500000	1.98568596	0.31396452	2.6440	78.0	0.0099
	B	40	-1.65000000	2.15489901	0.34071945			
DWOCF	A	40	-0.25000000	1.91819894	0.30329388	2.3578	78.0	0.0209
	B	40	-1.32500000	2.15296456	0.34041359			

indicates a mean improvement from the new drug of 1.325, which is significantly more ($p = 0.0209$, assuming equal variance) than the 0.25 from the placebo treatment, based on 40 subjects per treatment group.

Based on the results in Table 3, the 80 subjects entered in the study with comparable baseline disease symptoms ($p = 0.2080$). After 4 weeks, 29 and 28 subjects completed the study treatment of the placebo and the new drug, respectively. By analyzing the differences from baseline to week 4 (DW4), we see that the new drug provides a greater mean improvement than the placebo treatment. Using last observation carry-forward (DLOCF) analysis, the mean improvements from both treatment groups are less than those from the week 4 visit (1.65 vs. 1.786 for treatment B, 0.425 vs. 0.552 for treatment A). This fact indicates that the subjects who dropped out before week 4 tended to experience less improvement than the subjects who completed the 4-week treatment. As expected, worst observation carry forward (DWOFC) provides the least improvement among these three comparisons ($1.325 < 1.65 < 1.786$ for treatment B, and $0.25 < 0.425 < 0.552$ for treatment A). All three analyses (DW4, DLOCF, and DWOFC) provide consistent results that the new drug helps improve the disease symptom more than the placebo does.

In addition to the preceding analyses, these simulated data were used to perform the average change (DAVG) and slope analyses. Average change is computed by taking the mean of all postbaseline measures for each subject first and then subtracting the corresponding baseline of the subject. Let us use subject 1 as an example: this subject has scored 16, 20, 16, and 18 in weeks 1, 2, 3, and 4, respectively. The average of these four values is 17.5. Subtracting baseline 18 from 17.5 gives a DAVG of -0.5 for subject 1. A two-sample t -test is then applied to analyze these DAVG scores between treatment groups A and B.

Slope is estimated from each subject using simple linear regression (using PROC REG in the SAS software). These individual slopes are then used as the response variable in a two-sample t -test. The results from DAVG and SLOPE are given in Table 4.

The DAVG result in Table 4 indicates that the mean of average improvements are 1.15 for treatment B and 0.381 for treatment A, from 40 subjects of each treatment group. A two-sample t -test under the equal-variance assumption demonstrates a significant difference ($p = 0.0025$)

in favor of treatment B. For the SLOPE comparison, an F -test indicates the variance for treatment A is different from the variance for treatment B ($p = 0.006$). Hence an unequal-variance t -test is applied to compare these slopes. From the t -test, the mean slope of -0.5475 for treatment B is significantly different ($p = 0.0145$) from the -0.075 for treatment A, indicating a more rapid improvement can be obtained from the new drug, as compared to the placebo. Both DAVG results and SLOPE results are consistent with the findings from Table 3.

DISCUSSION

As mentioned previously, carry-forward analysis is one of the imputation methods used in analyzing clinical data. The primary advantages of carry-forward analysis include the following: It is convenient to implement for the intention-to-treat population, it is easy to communicate to nonstatisticians, and the results obtained from these analyses can be clearly interpreted. When an experimental drug is filed for regulatory approval, usually a large number of studies using various types of variables are combined to formulate an overall conclusion. In this case, a method applied consistently across different variables and studies can be very useful. Another advantage of carry-forward analysis is that this method can be consistently applied to all types of response variables and to different study designs.

However, there are a few disadvantages in the carry-forward methods. One of them is that the estimates obtained from these results can be biased. When the distribution of responses from subjects who completed the study is different from the distribution from those who dropped out, carry-forward analysis may provide biased estimates. The bias can affect the mean estimate, the variance estimate, or both. Biased estimates from carry-forward analysis may lead to incorrect conclusions from the study. Another disadvantage is that the carry-forward analysis may reduce power. When this is the case, clinical conclusions may also be misleading. The section on "Statistical Methods" cited an extreme case-imputing the best values for placebo-treated subjects and imputing worst values for test drug-treated subjects. Apparently, this method may create more bias.

Table 4 Additional Results from t -Tests

Variable	TRT	N	Mean	Standard deviation	Standard error	T	DF	Prob > T
DAVG	A	40	-0.38125000	0.92736329	0.14662901	3.1271	78.0	0.0025
	B	40	-1.15000000	1.24796130	0.19732001			
SLOPE	A	40	-0.07500000	0.58474189	0.09245581	2.5152	61.6	0.0145
	B	40	-0.54750000	1.03428100	0.16353418			

For H_0 : variances are equal, $F' = 3.13$, $DF = (39, 39)$, $\text{Prob} > F' = 0.0006$.

Shao and Zhang^[7] provided a systematic study of merits and limitations of the LCOF based on the ANOVA test. More discussion can be found in Chow and Shao.^[8]

As discussed previously, in addition to carrying forward the last observation, the worst observation, the best observation, or the baseline, a few other types of imputation can also be considered. The carry-forward weighted-average response and carry-forward linear-trend (slope) methods are illustrated in the section on “A Numerical Example.” Analysis using slope as the response variable is based on the assumption that the rate of change for each subject does not change after dropout. These variables can be analyzed using parametric or nonparametric methods, depending on distributional properties.

In general, imputation methods are frequently used in dealing with missing-data problems. Most of the advantages and disadvantages for imputation methods are similar to those for carry-forward analysis. Because these methods are widely used in application, Rubin^[9] developed multiple-imputation methods to overcome some of the disadvantages from single imputations. The idea of multiple imputation is to impute more than one possible value to each missing data point and to obtain multiple “imputed data sets.” Statistical analyses are then performed on these data sets, and results from the multiple analyses are combined to formulate inferences. A similar idea is to perform sensitivity analysis by examining results from many carry-forward analyses. In the section on “A Numerical Example,” analyses performed on the completers (DW4), DLOCF, DWOFC, average response, and individual slope all demonstrate similar results. This is a case where the clinical conclusion (that the new drug provides more benefit to the subject than the placebo does) can be supported from these analyses. In case different analyses demonstrate different results, further investigation will be needed to identify the reasons for the inconsistencies.

Before choosing appropriate methods to analyze clinical data, the statistician needs to consider the disease under study, the type of design, the study objective, the primary and secondary response variables for analysis, the distributional properties of these response variables, and the clinical interpretation of the results. Subjects often drop out of the study before completion. Under this circumstance, carry-forward methods can be considered for the data analysis. Parametric or nonparametric methods

can be used. When parametric methods are used—and in particular, linear or nonlinear models are chosen to perform the data analysis—potential covariates should be considered for inclusion in these models. Sometimes nonparametric analysis may be preferred.

CONCLUSION

Overall, carry-forward analysis is a useful tool in analyzing longitudinal clinical data with dropout problems. However, caution must be taken before choosing these methods and interpreting the analytical results. Sensitivity analysis often will be needed to check the robustness of clinical conclusions made from these analyses.

Case-Control Studies: Inference in

Gary King

Institute for Quantitative Social Science, Harvard University, Cambridge, Massachusetts, U.S.A.

Langche Zeng

Department of Political Science, University of California, San Diego, California, U.S.A.

Abstract

This entry is focused on developing methods that allow valid inferences about all relevant quantities of interest from either type of case-control study when completely ignorant of or only partially knowledgeable about relevant auxiliary population information.

Keywords: Case-control Studies; Data interpretation; Hazard rate; Logistic models; Number needed to treat; Odds ratio; Rate difference; Rate ratio; Relative risk; Risk difference; Risk ratio; Robust Bayesian inference; Statistics.

INTRODUCTION

Classic (or “cumulative”) case-control sampling designs do not admit inferences about quantities of interest other than risk ratios and then only by making the rare events assumption. Probabilities, risk differences, number needed to treat, and other quantities cannot be computed without knowledge of the population incidence fraction. Similarly, density (or “risk set”) case-control sampling designs do not allow inferences about quantities other than the rate ratio. Rates, rate differences, cumulative rates, risks, and other quantities cannot be estimated unless auxiliary information about the underlying cohort such as the number of controls in each full risk set is available. Most scholars who have considered the issue recommend reporting more than just risk and rate ratios, but auxiliary population information needed to do this is not usually available. We address this problem by developing methods that allow valid inferences about all relevant quantities of interest from either type of case-control study when completely ignorant of or only partially knowledgeable about relevant auxiliary population information.

OVERVIEW

Moynihan et al.^[1] express the conclusions of nearly all who have written about the standards of statistical reporting for academic and general audiences:

This is a somewhat revised and extended version of King, G.; Zeng, L. Estimating risk and rate levels, ratios, and differences in case-control studies. *Stat. Med.* **2002**, *21*, 1409–1427.

In general, giving only the absolute or only the relative benefits does not tell the full story; it is more informative if both researchers and the media make data available in both absolute and relative terms. For individual decisions ... consumers need information to weigh the probability of benefit and harm; in such cases it [also] seems desirable for media stories to include actual event [probabilities] with and without treatment.

Unfortunately, existing methods make this consensus methodological advice impossible to follow in the most used research design in many areas of medical research: case-control studies. In practice, medical researchers have historically used classic (i.e., “cumulative”) case-control designs along with the rare events assumption (i.e., that the exposure and non-exposure incidence fractions approach zero) to estimate risk ratios—or they abandon these quantities of interest altogether and merely report odds ratios. Although virtually no one supports the publication of odds ratios alone, this remains the dominant practice in the field.

In recent years, medical researchers have been switching to density sampling, which requires no such assumption for estimating rate ratios. (We discuss the failure-time matched version of density sampling called risk-set sampling by biostatisticians.) Unfortunately, researchers rarely have the population information needed by existing methods to estimate almost any other quantity of interest, such as absolute risks and rates, risk and rate differences, attributable fractions, or numbers needed to treat. We provide a way out of this situation by developing methods of estimating all relevant quantities of interest under classic and density case-control sampling designs when completely ignorant of, or only partially knowledgeable about, the relevant population information.

We begin with theoretical work on cumulative case-control sampling by Manski,^[2,3] who shows that informative bounds on the risk ratio and difference are identified for this sampling design even when no auxiliary population information is available. We build on these results and improve them in several ways to make them more useful in practice. First, we provide a substantial simplification of Manski's risk difference bounds, which also makes estimation feasible. Second, we show how to provide meaningful bounds for a variety of quantities of interest in situations of partial ignorance. Third, we provide confidence intervals for all quantities and a "robust Bayesian" interpretation of our methods that work even for researchers who are completely ignorant of prior information. Fourth, through the reanalysis of the hypothetical example from Manski's work and a replication and extension of an epidemiological study of bacterial pneumonia in individuals infected with human immunodeficiency virus (HIV), we demonstrate that adding information in the way we suggest is quite powerful as it can substantially narrow the bounds on the quantities of interest. Fifth, we extend our methods to the density case-control sampling design and provide informative bounds for all quantities of interest when auxiliary information on the population data is not available or only partially available. Finally, we suggest new reporting standards for applied research and offer software in Stata and in Gauss that implements the methods developed in this paper (available at <http://GKing.Harvard.edu>).

QUANTITIES OF INTEREST

For subject i ($i = 1, \dots, n$), define the outcome variable $Y_{i,(t,t+\Delta t)}$ as 1 when one or more "events" (such as disease incidence) occur in interval $(t, t + \Delta t)$ (for $\Delta t > 0$) and 0 otherwise. The variable t usually indexes time but can denote any continuous variable. In etiological studies, we shall be interested in $Y_{it} \equiv \lim_{\Delta t \rightarrow 0} Y_{i,(t,t+\Delta t)}$. In other studies, such as of perinatal epidemiology, conditions with brief risk periods such as acute intoxication, and some prevalence data, scholars only measure, or only can measure, $Y_{i,(t,t+\Delta t)}$, which we refer to as Y_i , because the observation period in these studies is usually the same for all i .^[4] Define a k -vector of covariates and constant term as X_i .^a In addition, let X_0 and X_c each denote k -vectors of possibly hypothetical values of the explanatory variables (often chosen so that the treatment variable changes and the others remain constant at their means).

Quantities of interest that are generally a function of t include the *rate* (or "hazard rate" or "instantaneous rate"), $\lambda_i(t) = \lim_{\Delta t \rightarrow 0} \Pr(Y_{i,(t,t+\Delta t)} = 1 | Y_{is} = 0, \forall_s < t, X_i) / \Delta t$, and functions of the rate. For example, the *rate ratio*, $rr_i = \lambda_c(t) / \lambda_0(t)$, and the

rate difference, $rd_i = \lambda_c(t) - \lambda_0(t)$, indicate how rates differ as the explanatory variables change from values X_0 to X_c .

Quantities of interest that are cumulated over an interval of time include the *risk* (also called the "probability" or "conditional probability of disease"),

$$\pi_i = \Pr(Y = 1 | X_i) = 1 - e^{-H(T_i, X_i)} = 1 - e^{-\int_t^{t+\Delta t} \lambda_i(s) ds} \quad (1)$$

[where $H(T_i, X_i)$ is the *cumulative hazard rate* for individual i over time interval $(t, t + \Delta t)$], the *risk ratio*, $RR \equiv \Pr(Y = 1 | X_c) / \Pr(Y = 1 | X_0)$, and the *risk difference* (or "first difference," as it is called in political science, or the "attributable risk," as economists and some epidemiologists call it), $RD \equiv \Pr(Y = 1 | X_c) - \Pr(Y = 1 | X_0)$. The probability is evaluated at some values of the explanatory variables, such as X_0 or X_c . The quantity RD is the increase in probability, and rr is the factor by which the probability increases [an $(RR - 1) \times 100$ percent increase] when the explanatory variables change from X_0 to X_c .

The quantities $\lambda(t)$, RR , RD , π , RR , and RD are normally used to study incidence in etiological analyses, but they are sometimes used to study prevalence by changing the definition of an "event." Functions of these quantities, such as the proportionate increase in the risk or rate difference, the attributable fraction, or the expected number of people needed to treat to prevent one adverse event (or, when the "treatment" has an adverse effect, the expected number of people needed to harm to result in one adverse event), can also be computed as a function of these quantities with the methods described below. For example, to compute the number needed to treat (NNT), we merely calculate:

$$MNT = \frac{1}{|RD|} \quad (2)$$

$$= \frac{1}{|\Pr(Y = 1 | X_c) - \Pr(Y = 1 | X_0)|} \quad (3)$$

That is, we simply use the reciprocal of the size of the risk difference between the "treatment" and "control" groups. The number needed to harm is obtained in the same way.

The other quantity frequently discussed and presented in the epidemiological literature is the *odds ratio*

$$\begin{aligned} OR &= \frac{\Pr(Y = 1 | X_c) / \Pr(Y = 0 | X_c)}{\Pr(Y = 1 | X_0) / \Pr(Y = 0 | X_0)} \\ &= \frac{\Pr(X_c | Y = 1) \Pr(X_0 | Y = 0)}{\Pr(X_0 | Y = 1) \Pr(X_c | Y = 0)} \end{aligned} \quad (4)$$

where the second equality holds by Bayes theorem. The main advantage of the OR is that it has been easier to

^aWe assume for the purpose of this paper that the X 's are not time-dependent.

estimate than the other quantities. In logit and other multiplicative intercept models (but not generally), the OR also has the attractive feature of being invariant with respect to the values at which control variables are held constant. The disadvantage of the OR is understanding what it means, and when or is not the quantity of interest—which is almost all the time—then its “advantages” are not sufficient to recommend its use. Some statisticians seem comfortable with the OR as their ultimate quantity of interest, but this is not common. Even more unusual is to find anyone who feels more comfortable with the OR than the other quantities defined above; we have found no author who claims to be more comfortable communicating with the general public using an OR than one of the other quantities.^[5] The OR has been used “largely because it serves as a link between results obtainable from follow-up studies and those obtainable from case-control studies.”^[6] We provide this link with other quantities so that the OR is no longer the only choice available.

Concluding a controversy on this subject in the *British Medical Journal*, Davies et al.^[7] write “On one thing we are in clear agreement: odds ratios can lead to confusion and alternative measures should be used when these are available.”

We show here how to make all relevant alternative measures *always* available, even in case-control data. With the results in this article, scholars should never again feel forced into presenting odds ratios.^b

CASE-CONTROL SAMPLING DESIGNS

We now introduce the two key case-control sampling designs. With appropriate modifications, most of the methods we introduce also work with many variants of them.

Classic (or *cumulative*) *case-control* designs involve sampling (usually all) “cases” (subjects for which $Y_i = 1$) and a random sample of “controls” (subjects for which $Y_i = 0$) at the end of the study period. This design is most appropriate in studies of closed populations and when Y_i but not Y_{it} is observed. Statistical models for such data specify the risk $\Pr(Y_i = 1|X_i)$ as a function of the input X_i . The most commonly used model is the logistic:

$$\Pr(Y_i = 1 | X_i) = \frac{1}{1 + e^{-X_i\beta}} \quad (5)$$

Some examples in medical research using the cumulative case-control design are studies of congenital malformation, analyses of “chronic conditions with ill-defined onset times and limited effects on mortality, such as obesity and multiple sclerosis, and studies of health services utilization”^[8]

and research that has as its goal descriptive, rather than causal, inferences (such as ascertaining the types of people that now have lung cancer so we can better prepare health-care facilities in anticipation).

The newer *density case-control* sampling design involves, in the study of cohort data organized by risk sets, sampling “cases” (subjects for which $Y_{it} = 1$) at their failure times and a subset of “controls” (subjects for which $Y_{it} = 0$) from all individuals at risk at the time of each failure, possibly matched on a set of other control variables. So each *sampled* risk set R_j ($j = 1, \dots, M$, where M is the total number of cases in the data) is composed of one case (or more in the case of timing ties in their occurrence) and a random sample of controls at the same time (or other continuous index) t . A subject may appear in multiple risk sets. This administratively convenient data collection strategy can result in a substantial reduction in the resources required for the study and also has the advantage of controlling non-parametrically (i.e., without functional form assumptions) for all omitted variables, and unmeasured heterogeneity, related to t . Statistical models for such data specify the incidence (hazard) rate as a function of t and X . The most commonly used model is the Cox proportional hazard:

$$\lambda_i(t) = \lambda(t)r(X_i, \beta) \quad (6)$$

where, in most applications, $r(X_i, \beta) = e^{X_i\beta}$ and the baseline hazard $\lambda(t)$ does not vary over subjects.^c

INFERENCE WITHOUT POPULATION INFORMATION

Classic Case-Control

Without additional population information or assumptions, the literature provides no method for estimating any quantity of interest from classic case-control data. Historically, medical researchers have used the *rare events assumption* to estimate the risk ratio by the odds ratio. Denote the population fraction of incident cases by τ , which is the key piece of auxiliary information about the population not reflected in the sample [although other quantities such as $P(X)$, the possibly multivariate density of X , are also sufficient]. The rare events assumption states that τ is arbitrarily small [while $P(X)$ stays bounded away from zero, or instead that $\Pr(Y_i = 1|X_i) \rightarrow 0$ for $j = 0, \ell$]. This assumption is not merely that cases are “rare,” but that they occur, at the limit, with zero probability. The advantage of this assumption is that, when correct, OR is a good approximation to the risk ratio: $\lim_{\tau \rightarrow 0} \text{OR} = \text{RR}$.

^bUnfortunately, the term “relative risk” no longer seems useful because it has been co-opted to denote such diverse quantities as RR and OR.

^cThe proportionality assumption holds when X_i is time-invariant. When this is not appropriate, a model that allows time-dependent covariates (such as the so-called Cox regression model) can be used.

This limit result is attractive because the OR is often easy to estimate in case-control designs. For example, if X is a single binary variable, or could be estimated by replacing elements in the second line of Eq. 4 with their sample analogs [e.g., $\Pr(X_i | Y = 1)$ can be estimated by the fraction of cases for which $X_i = X_c$ among all observations where $Y_i = 1$]. For another example, in logistic regression Eq. 5, case-control sampling only biases the intercept term, which drops out in the odds ratio expression, $OR = e^{(x_t - x_0)\beta}$. The coefficients of the control variables also drop out (because the elements of $X_c - X_0$ corresponding to those parameters are zero).

As is well known (e.g., Ref. [8]), the rare events assumption is problematic when τ is not nearly zero, and as a result, the odds ratio overestimates RR (when both are above 1; OR underestimates RR otherwise). In addition, this assumption implies, implausibly for most applications, that the risk difference tends to zero ($\lim_{\tau \rightarrow 0} RD = 0$), no matter how strong the real effect. In practice, RD is therefore not estimated, even when it is of more interest than RR.

When τ is very small but not zero, the bias introduced by using or as if it were RR can be ignored without practical consequence. The rare events assumption is inappropriate in etiology studies with more commonly occurring events, such as in highly infectious diseases. The assumption is also often not plausible when studying diseases with nonabsorbing states or when studying prevalence.

Density Case-Control

In the commonly used proportional hazard model (6), the coefficients β can be consistently estimated without any auxiliary information on the population risk sets. The contribution of each sampled risk set to the likelihood function is the ex ante incidence probability for the individual who will actually acquire the disease, conditional on the total number of cases in the set being one:

$$\Pr(Y_{it_j} = 1 | R_j) = \frac{\Pr(Y_{it_j} = 1)}{\sum_{k \in R_j} \Pr(Y_{kt_j} = 1)} = \frac{e^{x_{it}\beta}}{\sum_{k \in R_j} e^{x_{kt}\beta}} \quad (7)$$

where i indexes the case in the risk set and the summation in each denominator is over all observations in the risk set, $k = 1, \dots, n_j$, where n_j is the number of observations, or the size, of R_j . The likelihood function then is the product of terms such as Eq. 7 over all M sampled risk sets (see, e.g., Ref. [9]). When a risk set includes multiple cases, because of timing ties, the conditional probability expression is more complicated, but the approach remains the same. This same estimator was independently proposed in econometrics by Chamberlain^[10] to estimate consistently the parameters in a fixed-effect logit model when the number of subjects per group remains fixed even as the total number of subjects grows. Note also that Eq. 7 takes the same

form as the probability expressions in the popular multinomial logit model (or McFadden's choice model as some call it), and indeed the same software can be used on the data organized in risk sets to estimate β . Eq. 7 also takes the same form as the conditional probability expression for matched cohort data (for which Greenland^[11] gives an alternative modeling strategy for estimating the risk ratio).

Eq. 7 takes the same form as the likelihood function contribution of a *full* risk set in a Cox regression model for full cohort data, only that now the *sampled* risk sets are used. Fortunately, this does not bias the first-order condition and preserves the consistency and asymptotic normality of the maximum likelihood estimator (see Refs. [12–14]). Moreover, values of n_j of only about 6 can result in nearly full efficiency.^[12,15] For a discussion of biased selection of the controls, see Refs. [16,17] and see Ref. [18] for a discussion of alternative sampling designs.

With β consistently estimated by the conditional logit approach, we can compute the rate ratio using the incidence model (6), although the baseline hazard rate $\lambda(t)$ is not estimated:

$$rr = \frac{\lambda_t(t)}{\lambda_0(t)} = \frac{\lambda(t)e^{x_{it}\beta}}{\lambda(t)e^{x_{0t}\beta}} = \frac{e^{x_{it}\beta}}{e^{x_{0t}\beta}} = e^{(x_{0t} - x_{it})\beta} \quad (8)$$

Thus a key advantage of density designs over classic case-control designs is that we can estimate rr without any additional (rare events or other) assumptions or any population information. However, without auxiliary information on the population, the literature provides no method for estimating any other quantity of interest, such as the rate, rate difference, the risk, risk difference, risk ratio, or number needed to treat.

INFERENCE UNDER FULL POPULATION INFORMATION

We now discuss the quantities of interest that can be estimated under each sampling design when required auxiliary population information is available.

Classic Case-Control

In the classic case-control design, the population fraction of cases, τ , can supply the required auxiliary information.^[19–21] For example, in the simple case of a single binary explanatory variable, the risk can be estimated as

$$\begin{aligned} \pi &= \Pr(Y = 1 | X, \tau) \\ &= \frac{P(X | Y = 1) \Pr(Y = 1)}{P(X)} \\ &= \frac{P(X | Y = 1) \tau}{P(X | Y = 1) \tau + P(X | Y = 0) (1 - \tau)} \end{aligned} \quad (9)$$

where $P(X|Y = 1)$ and $P(X|Y = 0)$ are replaced with the sample mean of X among subjects where $Y = 1$ and $Y = 0$, respectively. From this expression, we can compute $RR = \Pr(Y = 1|X_{\tau})/\Pr(Y = 1|X_0, \tau)$, $RD = \Pr(Y = 1|X_{\tau}) - \Pr(Y = 1|X_0, \tau)$, or $NNT = 1/|rd|$.

For another example, the commonly used logistic regression model (5) on case-control data yields consistent maximum likelihood estimates of the slope coefficients and only the estimated intercept β_0 requires a correction such that the quantity estimated should instead be

$$\beta_0 - \ln \left[\left(\frac{1-\tau}{\tau} \right) \left(\frac{\bar{y}}{1-\bar{y}} \right) \right] \quad (10)$$

where $\bar{y}$ is the mean of Y or the sampling probability of $Y = 1$. Thus with exact knowledge of τ , all logit parameters can be consistently estimated (see Refs. [22–26]; see Ref. [19] for a comprehensive review). Let β_{τ} denote the logit coefficient vector, with the first element corrected as in Eq. 10. Then the quantities of interest are

$$\begin{aligned} \pi &= \Pr(Y = 1 | X, \tau) = [1 + e^{-X\beta_{\tau}}]^{-1}, \\ RR &= \frac{[1 + e^{-X_{\tau}\beta_{\tau}}]^{-1}}{[1 + e^{-X_0\beta_{\tau}}]^{-1}}, \\ RD &= [1 + e^{-X_{\tau}\beta_{\tau}}]^{-1} - [1 + e^{-X_0\beta_{\tau}}]^{-1}, \\ NNT &= \frac{1}{|RD|} \end{aligned}$$

For estimation, we can plug in the maximum likelihood estimates for β or use improved methods with lower mean square error in the presence of rare events.^[26] Standard errors for any of these quantities can be computed easily by simulation.^[27]

The correction in Eq. 10 applies not only to logit models, but also to any multiplicative intercept model, even including many neural networks (such as the feed-forward perceptron with a logit output function^[28,29]). Statistical research in medicine still predominately uses the logit specification for parametric analysis, whereas numerous other scholarly fields have been steadily switching to more flexible functional forms such as neural networks. In other fields, scholars have recognized that the logit model makes specific assumptions that are normally without substantive justification and indeed in the vast majority of research in this field are not even addressed explicitly. This is acknowledged in medical research in its use of matching models, but not when it comes to parametric approaches. Unfortunately, when using highly restrictive parametric forms such as logit, our empirical answers are functions of our theoretical specification rather than our data. By recognizing that the correction above applies to a much broader class of models, and makes considerably less stringent assumptions, researchers using case-control

designs will have many new and far more valid parametric approaches to choose from.

Density Case-Control

To estimate quantities of interest other than rr under density case-control sampling, we require information that enables the estimation of the baseline hazard rate. We employ the baseline hazard rate estimator proposed by Ref. [30] where the key population information needed is $\tau_j = n_j/N_j$, the sampling fraction for each observed risk set R_j ($j = 1, \dots, M$). With this information, and denoting the maximum likelihood estimate of β from the conditional logit procedure as b , the baseline incidence rate λ at time t_j is estimated as:^d

$$\lambda(t_j) = \frac{1}{\sum_{k \in R_j} (e^{X_k b}) (1/\tau_j)} = \frac{1}{\sum_{k \in R_j} e^{X_k b - \ln(\tau_j)}} \quad (11)$$

and with this, we can estimate the rate, $\lambda_i(t)$, from Eq. 6:

$$\lambda_i(t_j) = \frac{e^{X_i b}}{\sum_{k \in R_j} e^{X_k b - \ln(\tau_j)}} \quad (12)$$

With the rate, we can further estimate the cumulative rate:

$$H(T_i, X_i) = \sum_{t_j \in T_i} \lambda_i(t_j) = \sum_{t_j \in T_i} \sum_{k \in R_j} \frac{e^{X_i b}}{e^{X_k b - \ln(\tau_j)}} \quad (13)$$

and hence the risk:

$$\begin{aligned} \pi_i &= \Pr(Y = 1 | X_i) = 1 - e^{-H(T_i, X_i)} \\ &= 1 - \exp \left(- \sum_{t_j \in T_i} \sum_{k \in R_j} \frac{e^{X_i b}}{e^{X_k b - \ln(\tau_j)}} \right) \end{aligned} \quad (14)$$

and any of the other quantities of interest. The factor $1/\tau_j$ serves as a weighting factor that enables us to weight up each risk set to the full risk set size.

INFERENCE WITH BAYESIAN PRIOR ASSUMPTIONS

“Inference Without Population Information” and “Inference under Full Population Information” discuss inference under conditions of ignorance and full knowledge of the

^dThe proportionality assumption holds when X_i is time-invariant. When this is not appropriate, a model that allows time-dependent covariates (such as the so-called Cox regression model) can be used.

relevant auxiliary population information (τ and τ_j). When this information is not known exactly, but some prior information exists, Bayesian methods are appropriate and straightforward (although we are not aware of their use in applications in this context). Ideally, this prior information would come from registry or survey data from the target population, but similar information from closely related populations would help form reasonable priors also. The procedure is simply to put a prior distribution on τ (in classic case-control designs) or τ_j (in density case-control designs) and draw inferences about the quantity of interest from the posterior. These inferences have all the desirable properties of Bayesian estimates. They are consistent, efficient, asymptotically normal, and so on, when averaging over the prior. We strongly support their use when prior information is available and known to be valid.

Bayesian estimates also share at least two disadvantages. First, they are not calculable when the analyst is completely ignorant of τ or τ_j in some or all parts of its range because the required prior density cannot be fully specified, and, in Bayesian inference, one must have a full prior. Second, Bayesian estimates yield biased inferences when prior information is biased. This second problem is especially severe in case-control studies because the data contain *no* information about τ and τ_j , and so the prior does not become dominated by the likelihood as the sample size grows. That is, even for very large samples, inferences from case-control data depend heavily on the prior.

These disadvantages combine in unfortunate ways sometimes when analysts are unsure of the validity of their prior information. In these cases, the classic Bayesian paradigm may, in practice, have the effect of encouraging researchers to guess values for their prior, hence introducing biased information into their analyses and adversely affecting their inferences. “Diffuse” priors with large variances are also no solution here because in general, increasing the variance of τ or τ_j will also make the mean tend toward 0.5, which of course is a statement of knowledge, not ignorance.

We therefore pursue “robust Bayesian” methods below that allow full or partial ignorance to be represented accurately without biasing inferences.

INFERENCES WITHOUT FULL POPULATION INFORMATION OR ASSUMPTIONS: CLASSIC CASE-CONTROL

We now discuss inferences under classic case-control designs about π , RR, and RD without the rare events assumption or population information about τ . We begin by extending Manski’s results in the situation of pure ignorance and then add methods for partial ignorance, confidence intervals, and our preferred robust Bayesian interpretation. We conclude the section with two examples.

Extending Manski’s “Ignorance” Results

As an alternative to full knowledge of τ or the rare events assumption, Manski^[2,3] studied what inferences we could make when the researcher had no knowledge of τ . It is widely known that under these circumstances, no information about risk is available [i.e., $\pi \in (0,1)$] and RR is bounded between 1 and the OR. That is, $RR \in [\min(1,OR), \max(1,OR)]$, apart from sampling error. That this expression depends on the odds ratio is useful because of how often it is easily estimable.

Manski’s advance is that he also shows that RD can be bounded, although it requires the following complicated expression. Let

$$\phi = \left[\frac{\Pr(X_0 | Y=1)\Pr(X_0 | Y=0)}{\Pr(X_1 | Y=1)\Pr(X_1 | Y=0)} \right]^{\frac{1}{2}} \quad (15)$$

and

$$\gamma = \frac{a}{a - [\phi \Pr(X_1 | Y=1) - \Pr(X_0 | Y=1)]}, \quad (16)$$

where $a = \phi \Pr(X_1 | Y=0) - \Pr(X_0 | Y=0)$, and

$$RD_\gamma = \frac{\Pr(X_1 | Y=1)\gamma}{\Pr(X_1 | Y=1)\gamma + \Pr(X_1 | Y=0)(1-\gamma)} - \frac{\Pr(X_0 | Y=1)\gamma}{\Pr(X_0 | Y=1)\gamma + \Pr(X_0 | Y=0)(1-\gamma)} \quad (17)$$

Then RD is bounded between 0 and RD_γ , apart from sampling error, where RD_γ is the value of the risk difference if τ were equal to γ .

Manski’s expression for the risk difference is useful but only when it can be estimated. Unfortunately, except for very simple cases, sophisticated non-parametric methods are required to estimate each of the component probabilities in Eqs. 15–17], and ϕ , γ , and RD_γ are not easy to estimate directly; to our knowledge, they have never been estimated in a real application. We remedy this situation by showing, in [Appendix A](#), that these equations can be simplified so that $RD_\gamma = (\sqrt{OR} - 1) / (\sqrt{OR} + 1)$ (which, surprisingly, is exactly Yule’s^[31] “coefficient of colligation,” sometimes called Yule’s Y). The bounds are thus a simple function of the odds ratio:

$$RD \in \left[\min \left(0, \frac{\sqrt{OR} - 1}{\sqrt{OR} + 1} \right), \max \left(0, \frac{\sqrt{OR} - 1}{\sqrt{OR} + 1} \right) \right] \quad (18)$$

The advantages of our expression in Eq. 18 are not only algebraic simplicity and the familiarity with the odds ratio among applied researchers, but also that OR can be estimated very easily without non-parametric methods in simple discrete cases, in logistic regression, and in a wide

variety of multiplicative intercept models such as neural network models. Because these neural network models have arbitrary approximation capabilities, Eq. 18 can effectively always be applied.

A Proposed “Available Information” Assumption

Applied researchers have been reluctant to adopt Manski’s “ignorance” assumption, perhaps in part because the knowledge they have about τ is discarded entirely, often resulting in very wide bounds on the quantities of interest. Particularly uncomfortable for researchers is that no matter how strong the empirical relationship among the variables is, the bounds on RR always include 1 and on RD always include 0, which in both cases denote no treatment effect.

Thus existing literature effectively requires researchers to choose among three extreme assumptions: τ is essentially zero, is known exactly (possibly apart from sampling error), or is completely unknown. Our alternative approach is to elicit from researchers a range of values into which they are willing to say that τ must fall (e.g., [0.001, 0.05]), which appears to be a better reflection of the nature of prior information available in applied research settings than the extremes of exact knowledge or complete ignorance. Our approach seems consistent with Manski’s^[2] goals for future research and, like his specific methods, does not require a fully Bayesian prior distribution. Our approach could also be applied to bring available information and probabilistic inference to the methods Manski^[2] has offered in other areas.

Let π_τ , RR_τ , RD_τ , and NNT_τ denote values of the probability, relative risk, risk difference, and number needed to treat, respectively, evaluated at τ . Suppose that τ is known only to fall within the range $[\tau_0, \tau_1]$, where $0 < \tau_0 < \tau_1 < 1$. (Because, by definition, choice-based samples include at least one example of a case and one of a control, τ_0 and τ_1 are known not to equal zero or one exactly.) Then, because π and rr are monotonic in τ , their bounds are simply

$$\pi \in [\pi_{\tau_0}, \pi_{\tau_1}] \quad (19)$$

and

$$RR \in [\min(RR_{\tau_0}, RR_{\tau_1}), \max(RR_{\tau_0}, RR_{\tau_1})] \quad (20)$$

The bounds for the risk difference are more complicated because RD_τ is a parabolic function of τ , and so the bounds differ in the monotonic and nonmonotonic regions. The relationship is monotonic in regions where τ_0 and τ_1 are both greater than or both less than the value of τ that corresponds to $RD_\tau = (\sqrt{OR} - 1)/(\sqrt{OR} + 1)$. This region corresponds to cases where the derivative of RD_τ with respect to τ , evaluated at τ_0 and τ_1 , have the same sign. (This derivative can easily be checked numerically by comparing the signs of $RD_{\tau_0+\epsilon} - RD_{\tau_0}$ and $RD_{\tau_1+\epsilon} - RD_{\tau_1}$

for a suitably small value of ϵ .) When the relationship is monotonic, the bounds are

$$RD \in [\min(RD_{\tau_0}, RD_{\tau_1}), \max(RD_{\tau_0}, RD_{\tau_1})] \quad (21)$$

and otherwise, they are

$$RD \in [\min(RD_{\tau_0}, RD_{\tau_1}, RD_\gamma), \max(RD_{\tau_0}, RD_{\tau_1}, RD_\gamma)] \quad (22)$$

The bounds for number needed to treat can be directly derived from those for the risk difference by using reciprocals of the latter.

Revisiting a Numerical Example

We illustrate our methods by extending the numerical example concerning smoking and heart disease given by Manski.^[2,3] For clarity, we follow Manski in ignoring uncertainty (i.e., equating sample fractions with sampling probabilities as if $n \rightarrow \infty$) in this section (only); in the next two sections, we show how to include estimation uncertainty and compute confidence intervals. This section also demonstrates the degree to which results under our approach are sensitive to assumptions about the interval $[\tau_0, \tau_1]$ while holding constant (at zero) estimation uncertainty. (The effect of estimation uncertainty, while holding constant the interval, follows standard sampling theory.)

In Manski’s example, X is a binary explanatory variable taking values 1 for smokers and 0 for non-smokers, and Y takes on the values 1 for coronary heart disease and 0 for healthy individuals. The assumptions in his example imply that $\Pr(X = 1|Y = 1) = 0.6$, $\Pr(X = 1|Y = 0) = 0.49$, $\Pr(X = 0|Y = 1) = 0.4$, and $\Pr(X = 0|Y = 0) = 0.51$. Hence using Eq. 9, we can write the probabilities as functions of τ :

$$\begin{aligned} \Pr(Y = 1 | X = 1, \tau) &= \frac{0.6\tau}{0.6\tau + 0.49(1-\tau)} \\ &= \frac{\tau}{0.82 + 0.18\tau} \\ \Pr(Y = 1 | X = 0, \tau) &= \frac{0.4\tau}{0.4\tau + 0.51(1-\tau)} \\ &= \frac{\tau}{1.28 - 0.28\tau} \end{aligned}$$

For each of the quantities of interest, we now compare the case where τ is unknown, as Manski does, to where it is known to lie in the interval [0.05, 0.15] (Manski’s example implies that $\tau = 0.1$, which he treats as not known). Without bounds on τ , the problem provides no information about any probability, whereas the additional information about τ gives much more informative bounds: the probability of heart disease among smokers is $\Pr(Y = 1|X = 1) \in [0.06, 0.18]$, whereas among non-smokers, it is $\Pr(Y = 1|X = 0) \in [0.04, 0.12]$. For risk ratio, Manski’s “ignorance”

assumption gives $RR \in [1., 1.57]$, whereas our alternative approach implies the very tight bounds of $RR \in [1.46, 1.53]$, indicating that smoking increases the risk of heart disease between 46% and 53%. For the risk difference, the bounds given no information on τ are $RD \in [0, 0.11]$, whereas our approach yields much narrower bounds of $RD \in [0.021, 0.056]$, the increase in probability due to smoking. Because smoking has an adverse effect, we can also obtain bounds for NNT, the number needed to harm, based on that for the risk difference. With no information on τ , Manski's approach would result in $NNT \in [9, \infty]$, which is hardly informative at all, while our method gives $NNT \in [18, 48]$, a range infinitely narrower than "between 9 and infinity" and of course more substantively meaningful.

Classical Confidence Intervals

We now provide a method of computing classical confidence intervals, saving our preferred robust Bayesian interpretation for the following section. Because each end of the bounds on π , RR , and RD are measured with error, upper and lower confidence intervals could be computed and reported for each. However, the inner bounds (the upper confidence limit on the lower bound and the lower confidence limit on the upper bound) are not of interest. Thus we recommend defining a confidence interval (CI) as the range between the outer confidence limits. The actual CI coverage of the resulting interval is always at least as great as the nominal coverage.

For all methods provided above, confidence intervals can easily be computed by simulation (the delta method is also possible but difficult because of the discontinuities caused by the minimum and maximum functions). The bounds are known functions of, and derive their sampling distributions from, the estimated model parameters. Therefore the distribution of the bounds can be simulated using random draws from the sampling distributions of the parameters.^[27] For example, in the logit model, the asymptotic distribution of the estimated parameters is normal with mean vector and covariance matrix estimated by the usual maximum likelihood procedures. Random draws from this distribution can then be converted into random draws from the distribution of the bounds through the relevant formulas relating the bounds and the model parameters. A 90% (for example) CI for the bounds can be obtained by sorting the m random draws of the bounds and taking the 5th and 95th percentile values as the lower and upper bounds, respectively. Our software implements these procedures. The choice of m reflects the tradeoff between accuracy and speed: larger values of m improve accuracy and reduce speed. The required m depends on the example; 1000 will often be enough, but it is easy to verify: rerun the simulation and if anything changes in as many significant digits as is needed, increase m and try again.

A Robust Bayesian Interpretation

Our estimation procedure is not strictly Bayesian in that choosing an interval for τ is not equivalent to imposing a uniform (or any version of a "non-informative") prior density within those bounds. However, our procedure can be thought of as a special case of "robust Bayesian analysis" (e.g., Refs. [32, and 33]) and one that happens to be easier to apply and gives results that are considerably easier for applied researchers to use than most examples in this literature.

From this robust Bayesian perspective, the interval chosen for τ can be thought of as narrowing the choice of a prior to only a class of densities rather than a (fully Bayesian) single density. In our case, the class of priors is defined to include all densities $P(\tau)$ subject to the constraint that $\int_{\tau_0}^{\tau_1} P(\tau) d\tau = 1$. The advantages of this approach are that prior elicitation is much easier, it does not force analysts to give priors when no prior information exists, and, more importantly, estimates depend only on real information and so are the same for any density within the class. If a classical Bayesian prior is inaccurate, classical Bayesian inferences will be incorrect. In contrast, our "robust Bayesian" approach will give valid inferences even if we can only narrow the prior to a class of densities rather than one particular density function. (Because data do not help in making inferences about τ , this model is an example of the type of analysis for which Berger^[32] argues that robust Bayesian analysis is required.)

The cost of this approach is that the information about our quantity of interest can only be narrowed to a class of posterior densities. Fortunately, in the present case, this class can be conveniently summarized as an inequality (rather than an equality) statement regarding the credible intervals: the probability that the actual quantity of interest is within the computed interval is always at least as great as the nominal coverage.*

Thus reporting results from our methods can be as simple as from existing methods used in this field. This is a considerable advantage over other applications of robust Bayesian methods because although considerable research

*One objection to our procedure is that assuming a zero prior probability for τ outside the interval $[\tau_0, \tau_1]$ may be unrealistic. Of course, one may simply enlarge the prior interval to include the nonzero density area, but a probabilistic version is easy to construct: first, elicit the interval endpoints, τ_0 and τ_1 , and also a fraction α (e.g., 0.05) such that $1 - \alpha$ fraction of the time τ falls within $[\tau_0, \tau_1]$, i.e., $\int_{\tau_0}^{\tau_1} P(\tau) d\tau = 1 - \alpha$. Then, outside this interval, use a portion of a (single) density to allocate the remaining probability to $[0, \tau_0)$ and $(\tau_1, 1]$, so that the sum of the integrals of the two add to α . In this way, every member of the class of densities on the full interval $[0, 1]$ is proper, and robust Bayesian analysis can proceed as before. We have found these changes inconsequential in the real applications we have studied, although our software offers the option to handle this situation.

in statistics has focused on these approaches, applications are still fairly rare. The reason is that the class of priors turns into a class of posteriors, and it is the entire class of posteriors that constitutes the research results. Summarizing a single multi-dimensional posterior is already fairly difficult; summarizing a class of posteriors in multi-dimensional space only creates more problems. Yet in our case, the class of posteriors can be reduced for presentation purposes to a credible interval, the only disadvantage of which is that it provides an inequality rather than equality statement.

An Empirical Example

We now reanalyze data provided in Tumbarello et al.,^[34] the largest case-control study ever conducted of the risk factors leading to bacterial pneumonia in HIV-infected patients. We focus on their univariate analysis of risk factors in 350 cases and 700 controls. The authors report prior knowledge of τ (the fraction of HIV-seropositive individuals in the general population who have an episode of bacterial pneumonia), based on previous studies, as falling in the interval [0.097, 0.29]. We interpret this to be a 99% prior interval and, for simplicity, assume the remaining $\alpha = 0.01$ mass to be uniform in [0, 0.097] and (0.29, 0.6]; our experiments (not shown) indicate that inferences change very little across many reasonable choices for the density outside the [0.097, 0.29] interval for τ .

The first row of Table 1 replicates the CI for the univariate odds ratio reported in Ref. [34] for each of four risk factors they considered. The second row of the table gives $\geq 95\%$ CIs for the risk ratio of each risk factor, using the robust Bayesian methods described in “A Robust Bayesian Interpretation” (with $m = 1000$ simulations). As the table shows, the intervals for RR indicate somewhat smaller effects than the OR, with the most noticeable effects for IV drug use and smoking.

Perhaps more interesting are the final three rows of the table, which offer information not reported in any form in the original article. For example, Table 1 shows that smoking increases the probability of bacterial pneumonia

between 0.05 and 0.27 ($\alpha \geq 95\%$ CI for the risk difference, RD). For another example, the $\geq 95\%$ CI for the base probability of an IV drug user contracting bacterial pneumonia is 0.10–0.38. These examples and the other information in Table 1 all seem like valuable information for researchers and others interested in the study and its results. The information existed in the data from this study, but they are revealed only by application of the methods offered here.

INFERENCE WITHOUT FULL POPULATION INFORMATION OR ADDITIONAL ASSUMPTIONS: DENSITY CASE-CONTROL

We now give analogous results for density case-control designs to those provided in “Inferences Without Full Population Information or Assumptions: Classic Case-Control” for classic case-control designs and provide informative bounds for π , RR, RD, $\lambda_i(t)$, and rd_i when no information or only partial information is available about the τ_j ’s in “Inference under Full Population Information” (we skip rr_i because it does not depend on τ_j and is estimable from the conditional logit procedure). Inference from density case-control samples is complicated by the fact that more than one piece of population information is involved: there is a τ_j associated with each of the M risk sets.^f We elicit the minimum and maximum values of each τ_j , which we denote $\underline{\tau}_j$ and $\bar{\tau}_j$, respectively. The interval $(\underline{\tau}_j, \bar{\tau}_j]$ can change with j or can be constant over risk sets; it can be specified to include 100% of the prior density, as in “A Proposed ‘Available Information’ Assumption,” or $1 - \alpha$ fraction of the density, as in “A Robust Bayesian Interpretation.” When we are completely ignorant over τ_j , the interval is (0, 1].

To simplify notation, let $r_k = e^{v_{kb}}$ and $r^j = \sum_{k \in R_j} r_k$. Clearly $r_k > 0$ and $r^j > 0 \forall k, j$. Then the estimators for the rate,

^fSee Ref. [35] for methods for estimating the risk using only the overall cohort disease rate. However, this estimator is less efficient than the one proposed by Langholz and Ornulf[30] and employed here. See also Ref. [6] on estimating rates using information on the crude incidence density.

Table 1 Replication and Extension of 95% CIs

Quantity of interest	Risk factor			
	IV drug use	Smoking	Pneumonia	Cirrhosis
OR	1.44–2.70	1.81–3.64	1.01–1.88	1.01–2.49
RR	1.31–2.45	1.52–3.13	1.01–1.73	1.03–2.17
RD	0.03–0.19	0.05–0.27	0.00–0.13	0.00–0.20
Pr($Y = 1 X = 0$)	0.05–0.26	0.05–0.26	0.08–0.31	0.08–0.31
Pr($Y = 1 X = 1$)	0.10–0.38	0.13–0.47	0.09–0.40	0.10–0.50

The OR row is an exact replication and the others are extensions using the methods developed here. The last two rows give the probability of contracting bacterial pneumonia given the absence and presence of the given risk factor, respectively. (From Ref. [34].)

cumulative rate, and risk in Eqs. 12–14, respectively, can be rewritten as:

$$\lambda_i(t_j) = \frac{r_i \tau_j}{r^j} \quad (23)$$

$$H(T_i, X_i) = \sum_{t_j \in T_i} \lambda_i(t_j) = \sum_{t_j \in T_i} \frac{r_i \tau_j}{r^j} \quad (24)$$

and

$$\pi_i = \Pr(Y = 1 | X_i) = 1 - e^{-H(T_i, X_i)} = 1 - \exp\left(-\sum_{t_j \in T_i} \frac{r_i \tau_j}{r^j}\right) \quad (25)$$

respectively. We now develop bounds for the quantities of interest as functions of τ_j and $\bar{\tau}_j$.

Risk

From Eq. 25, we have $\frac{\partial \pi_i}{\partial \tau_j} = \frac{e^{-H(T_i, X_i)} r_i}{r^j} > 0 \quad \forall_j$ hence the risk is a monotonically increasing function with respect to every τ_j . Denote $\underline{\pi}_i$ and $\bar{\pi}_i$ as the values of π_i with all τ_j set to τ_j and $\bar{\tau}_j$, respectively; then the bounds for π_i are simply $\pi_i \in [\underline{\pi}_i, \bar{\pi}_i]$. For example, when we are completely ignorant about τ_j and therefore $(\tau_j, \bar{\tau}_j)$ is $(0, 1]$, the bounds give $\pi_i \in (0, 1 - \exp(-\sum_{t_j \in T_i} (r_i/r^j))]$.

Risk Ratio

We now examine $RR = \pi_1/\pi_0$, where π_i is as in Eq. 25, $i = 0, 1$. We have

$$\frac{\partial RR}{\partial \tau_j} = \frac{r_1(1 - \pi_1)\pi_0 - r_0(1 - \pi_0)\pi_1}{\pi_0^2 r^j} \quad (26)$$

the sign of which is determined by that of the numerator. When the numerator is positive, i.e., when

$$rr = r_1/r_0 > \frac{\pi_1(1 - \pi_0)}{(1 - \pi_1)\pi_0} = OR \quad (27)$$

the partial derivative is positive and so RR increases with respect to τ_j . Otherwise, the derivative is negative and RR decreases with respect to τ_j . In [Appendix B](#), we show that Eq. 27 holds whenever $rr < 1$, independent of the values of τ_j . Similarly, the sign is reversed whenever $rr > 1$. Hence RR is either monotonically increasing or monotonically decreasing with respect to τ_j for all j .

Thus when $rr < 1$, rr is monotonically increasing with respect to all τ_j and is therefore bounded by $\underline{RR}$ and $\bar{RR}$, which are values of RR with all τ_j set to their minimum and maximum values, respectively. Otherwise, RR is monotonically decreasing and the bounds are $\bar{RR}$ and $\underline{RR}$. In short, RR is bounded by

$$RR \in [\min(\underline{RR}, \bar{RR}), \max(\underline{RR}, \bar{RR})] \quad (28)$$

It is easy to see that $\lim_{\tau_j \rightarrow 0} RR = r_1/r_0$, hence when no information is available for τ_j and therefore $(\tau_j, \bar{\tau}_j)$ is $(0, 1]$, the bounds become $RR \in (\min(r_1/r_0, \bar{RR}), \max(r_1/r_0, \bar{RR})]$ where $\bar{RR}$ is RR evaluated at $\tau_j = 1 \quad \forall_j$.

Risk Difference

The case of $RD = \pi_1 - \pi_0$ is more complicated because RD is not a monotonic function of the τ_j 's and $\partial RD/\partial \tau_j = [r_1 e^{-H(T_1, X_1)} - r_0 e^{-H(T_0, X_0)}]/r^j$ can change signs depending on the values of τ_j . Under the proportional hazards model where r_i and r^j are not functions of time, however, we can reduce the analytically difficult or even intractable problem of constrained optimization in multi-dimensional space to a simple one in which RD is a one-dimensional function of the cumulative baseline hazard, which is a monotone function of the τ_j 's.

Let $Q(\tau_j) = \sum_{t_j} M \tau_j / r^j$ denote the cumulative baseline hazard rate, and note that $\partial Q(\tau_j)/\partial \tau_j = 1/r^j > 0$ for all j , so $Q(\tau_j)$ is monotonically increasing in all τ_j 's and therefore bounded between $\underline{Q} = Q(\tau_j)$ and $\bar{Q} = Q(\bar{\tau}_j)$. Now rewrite RD in terms of Q . From Eq. 24, we have $H(T_k, X_k) = r_k Q$ for $k = 0, 1$; hence

$$RD = (1 - e^{-r_1 Q}) - (1 - e^{-r_0 Q}) = e^{-r_0 Q} - e^{-r_1 Q} \quad (29)$$

and

$$\frac{\partial RD}{\partial \tau_j} = \frac{r_1 e^{-r_1 Q} - r_0 e^{-r_0 Q}}{r^j} \quad (30)$$

RD is not monotone in Q , but Q is a scalar and we know its bounds, which brings us to a situation mathematically similar to analyzing RD in classic case-control designs.

Let Q^* be the solution to the first-order condition $\partial RD/\partial \tau_j = 0$. From Eq. 30, we can solve for $Q^* = [1/(r_1 - r_0)] \ln(r_1/r_0)$. Then from Eq. 29, we have

$$RD(Q^*) = (r_0/r_1)^{r_0/(r_1-r_0)} - (r_0/r_1)^{r_1/(r_1-r_0)} \quad (31)$$

To obtain the bounds for RD, we first see whether $\underline{Q}, \bar{Q}$ contains Q^* . If it does, then

$$RD \in [\min(\underline{RD}, \bar{RD}, RD^*), \max(\underline{RD}, \bar{RD}, RD^*)] \quad (32)$$

where $\underline{RD} = RD(\underline{Q})$, $\bar{RD} = RD(\bar{Q})$, and $RD^* = RD(Q^*)$. Otherwise, the bounds are

$$RD \in [\min(\underline{RD}, \bar{RD}), \max(\underline{RD}, \bar{RD})] \quad (33)$$

When no information is available for τ_j , the bounds become

$$RD \in [\min(0, RD^*), \max(0, RD^*)] \quad (34)$$

Rate

From Eq. 23, we see that $\partial\lambda_i(t_j)/\partial\tau_j = r_i/r^j > 0$; hence $\lambda_i(t_j)$ is monotonically increasing in τ_j . It is therefore bounded in $(\lambda_i(t_j), \overline{\lambda_i(t_j)})$, where $\lambda_i(t_j)$ is $\lambda_i(t_j)$ evaluated at $\underline{\tau}_j$ and $\overline{\lambda_i(t_j)}$ is $\lambda_i(t_j)$ evaluated at $\overline{\tau}_j$. When we are ignorant with respect to the τ_j 's, the rate is bounded as $(0, r_i/r^j)$.

Rate Difference

Because $\partial rd/\partial\tau_j = (r_1 - r_0)/r^j$, rd is monotonically increasing in τ_j if $r_1 > r_0$ and decreasing otherwise. Hence the bound on the rate difference is

$$rd \in \left[\min \left[rd(\underline{\tau}_j), rd(\overline{\tau}_j) \right], \max \left[rd(\underline{\tau}_j), rd(\overline{\tau}_j) \right] \right] \quad (35)$$

and when ignorant of all information on τ_j , the bounds are

$$rd \in \left[\min \left[0, (r_1 - r_0)/r^j \right], \max \left[0, (r_1 - r_0)/r^j \right] \right]$$

CONCLUSION

As is increasingly recognized, the quantity of interest in most case-control studies is not the odds ratio, but rather some version or function of a probability, risk ratio, risk difference, rate, rate ratio, or rate difference, depending on context.^[6,7,36–41] We provide the methods to estimate each of these quantities from case-control studies, even if no auxiliary information, or only limited auxiliary information, is available.

Unless the odds ratio happens to approximate a parameter of central substantive interest, which is quite rare, we suggest that it should not be reported any more frequently than any other intermediate quantity in statistical calculations. We suggest instead that researchers justify their assumption regarding bounds on τ (in classic case-control studies) or τ_j (in risk set case-control studies) in the data or methods section of their work. Then, they can substitute the confidence interval (CI) now reported for the odds ratio with the CI for their chosen quantity (or quantities) of interest. For example, instead of an uninformative but presently common reporting style:

the effect of smoking on lung cancer is positive OR = 1:38
(95% CI 1.30–1.46)

researchers could give the much more interesting:

smoking increases the risk of contracting lung cancer by a factor of between 2.5 and 3.1 ($\alpha; \geq 95\%$ CI)

or

smoking increases the probability of contracting lung cancer between 0.022 and 0.051 ($\alpha; \geq 95\%$ CI)

If uncertainty exists over the appropriate bounds for the unknown quantities, we suggest using the widest bounds,

conducting sensitivity analyses by showing how the CI depends on different assumptions or setting α to a value other than zero.

The methods discussed here are meant to improve presentation and increase the amount of information that can be extracted from existing models and data collections. They do not enable scholars to ignore the usual threats to inference (measurement error, selection bias, confounding, etc.) that must be avoided in any study.

ACKNOWLEDGMENTS

We thank Sander Greenland for his generosity, insight, and wisdom about the epidemiological literature, Norm Breslow and Ken Rothman for many helpful explanations, and Chuck Manski for his suggestions, provocative econometric work, and other discussions. Thanks also to Neal Beck, Rebecca Betensky, Josué Guzmán, Bryan Langholz, Meghan Murray, Adrain Rafferty, Ted Thompson, Jon Wakefield, Clarice Weinberg, and David Williamson for helpful discussions, Ethan Katz for research assistance, and Mike Tomz for spotting an error in an earlier version. Software to implement the methods in this paper is available for R, Stata, and Gauss from <http://GKing.Harvard.Edu>.

APPENDIX A: SIMPLIFYING MANSKI'S BOUNDS ON THE RISK DIFFERENCE

Proving Eq. 18 requires algebra only. For simplicity, let $P_{ab} = \Pr(X_a|Y = b)$, so that OR = $(P_{11}P_{00})/(P_{01}P_{10})$. Then, omitting tedious but straightforward algebra at several stages, $\phi = (ORP_{01}^2/P_{11}^2)^{1/2} = \sqrt{OR} P_{01}/P_{11}$, and $\gamma = \sqrt{OR}/(\sqrt{OR} + P_{11}/P_{10})$. Then the components of RD γ are

$$P_{11}\gamma = \frac{\sqrt{OR}P_{10}P_{11}}{\sqrt{OR}P_{10} + P_{11}}, \quad P_{01}\gamma = \frac{\sqrt{OR}P_{01}P_{10}}{\sqrt{OR}P_{10} + P_{11}}$$

$$P_{10}(1-\gamma) = \frac{P_{10}P_{11}}{\sqrt{OR}P_{10} + P_{11}}, \quad P_{00}(1-\gamma) = \frac{P_{11}P_{00}}{\sqrt{OR}P_{10} + P_{11}}$$

and so putting the terms together yields

$$RD_\gamma = \sqrt{OR}/(1 + \sqrt{OR}) - 1/(1 + \sqrt{OR})$$

$$= (\sqrt{OR} - 1)/(\sqrt{OR} + 1).$$

APPENDIX B: MONOTONICITY OF RISK RATIO UNDER DENSITY CASE-CONTROL DESIGNS

We show here that if $rr < 1$, then $rr > [\pi_1(1 - \pi_0)]/[(1 - \pi_1)\pi_0]$ (the $r_1/r_0 > 1$ case is similar). Let $H_k = H(T_k, X_k)$, $k = 0, 1$. From the definition of π_1 and π_0 , $[\pi_1(1 - \pi_0)]/[(1 - \pi_1)\pi_0]$ can be simplified to $(e^{H_1} - 1)/(e^{H_0} - 1)$. Because $rr = H_1/H_0$, we only need to show that if $H_1/H_0 < 1$, then $H_1/H_0 > (e^{H_1} - 1)/(e^{H_0} - 1)$ or, equivalently,

$$H_1(e^{H_0} - 1) > H_0(e^{H_1} - 1).$$

The e^{H_1} Taylor series expansions of $e^{H_1} - 1$ and $e^{H_0} - 1$ at 0 give

$$e^{H_1} - 1 = H_1 + (1/2)H_1^2 + (1/3!)H_1^3 + \dots \quad (36)$$

$$e^{H_0} - 1 = H_0 + (1/2)H_0^2 + (1/3!)H_0^3 + \dots \quad (37)$$

and hence

$$H_1(e^{H_0} - 1) = H_1H_0 + (1/2)H_0^2H_1 + (1/3!)H_0^3H_1 + \dots \quad (38)$$

$$H_0(e^{H_1} - 1) = H_0H_1 + (1/2)H_1^2H_0 + (1/3!)H_1^3H_0 + \dots \quad (39)$$

The first terms in Eqs. 38 and 39 are equal, and when $H_1/H_0 < 1$, hence $H_1 < H_0$, all other terms in Eq. 38 are greater than the corresponding terms in Eq. 39 (because both $H_0 > 0$ and $H_1 > 0$ always). Thus when $H_1/H_0 < 1$, $H_1(e^{H_0} - 1) > H_0(e^{H_1} - 1)$.

Center Weighting: Multicenter Trials

Paul Gallo

Biostatistics, Novartis Pharmaceuticals Corporation, East Hanover, New Jersey, U.S.A.

Abstract

The primary motivation for using multiple centers is to enable enrollment of a sufficient number of clinical trial patients to investigate a hypothesis in a timely manner. This entry reviews the advantages of center weighting in multicenter trials, looks at the construction of composite centers, and discusses the regulatory guidelines of such trials.

Keywords: Fixed effect model; Multicenter trial; Random effect model; Treatment-by-center interaction.

INTRODUCTION

Clinical trials comparing treatment therapies are commonly conducted using patients from a number of different sites. The primary motivation for using multiple centers is to enable enrollment of a sufficient number of patients to investigate a hypothesis in a timely manner. A beneficial consequence is that this can provide evidence that the trial results are not strongly setting dependent; hence, it may be reasonable to interpret that these results apply to a broader population of clinical sites or patient populations. Some statistical analysis methods as applied to data from multicenter clinical trials can be formulated as combinations of treatment effect estimates or test statistics determined within the individual centers. There can thus be some ambiguity in how these within-center estimates should be combined; this issue may be described in terms of weights associated with the individual centers. For example, inference may be based on an overall treatment effect estimate that simply averages the within-center estimates, so that we might view the resultant analysis as using equal center weighting. Alternatively, since differing within-center sample sizes may lead to different precisions of the center-specific estimates, we might combine the within-center estimates according to some measure of their precision (i.e., more precise estimates—generally those from larger centers—receive more weight). Other formulations can be considered as well. Later sections describe various issues relating to center weighting in analysis of clinical trial data, and consider statistical, logistic, and regulatory aspects and implications.

STATISTICAL FRAMEWORK

A feature of multicenter trials with important implications for statistical analysis is that it is a natural consequence

of the manner in which such trials are conducted that the within-center sample sizes can be quite different from each other. Trials in which the largest center contributes 4 or 5 times as many patients as the smallest are quite common, and larger imbalances are often encountered. Attempting to enforce similarity of center sample sizes can substantially lengthen trial duration and increase potential for subtle selection biases as well.^[1]

Typically, statistical analysis models for clinical trial data take into account the site at which a patient was enrolled, i.e., analysis models are used that adjust expected response for center. Depending on the data structure and analysis method used, center might be included as a covariate, or perhaps might define strata in a stratified analysis. One main reason for such adjustment is that for logistical reasons, it is common for randomization schemes to be stratified within center, and it is considered good statistical practice for analysis models to reflect restrictions on randomization resulting from stratification.^[2] Additionally, the center at which a patient enrolled may well be predictive of response because of differences in investigator skills, local medical practices, patient populations, etc. (though when such effects are really due to other identifiable and measurable covariates, it will often be advisable to consider adjusting for those also—accounting for center in analysis models should not be viewed as a justification for not having adjusted for other variables expected to be meaningful). At another level, the consistency of treatment differences across centers and other key subgroups will generally be of value in fully interpreting trial results; hence treatment-by-center interaction will usually be of some interest to investigate. The rationale from a regulatory perspective for interest in center consistency and its relevance to the interpretation of the trial results as a whole is well described in Ref. [3].

Questions regarding how analysis models should account for centers are closely related to issues of “weights” that centers receive in the analysis. A partial list of articles on multicenter trial analysis with some relationship to this issue includes.^[3–16] Much of this literature discussion has played out in the specific case of analyses that utilize fixed-effect analysis of variance (ANOVA) models for normally distributed data, in which the principles and mechanics are most easily illustrated. This issue is closely related to the definition of different “types” of ANOVA sums of squares produced by the procedure PROC GLM in the SAS statistical software system,^[17] and also to the question of whether or not a term for treatment-by-center interaction is included in the statistical model. This framework is our main focus here, though these issues certainly have relevance for other data types (e.g., binary or categorical outcomes, time-to-event data), and later we discuss this issue a bit further. Within the ANOVA framework, we also discuss later random-effect models, in which center main effects or interactions with treatment are considered to be random variables; these present an intriguing alternative to fixed effect models and are very relevant to the general issue of center weighting.

For ease of illustration, we restrict consideration to a comparison between two treatment groups in a number of centers denoted by c . For further simplicity, assume that there are no covariates predictive of outcome under consideration other than treatment and center; the basic ideas extend readily to more complex formulations. We let R_{ijk} denote a response variable for a particular patient k randomized to treatment group i at center j , $i = 1, 2; j = 1, \dots, c$. We let n_{ij} denote the number of patients in center j assigned to treatment group i ; also, $n_j = n_{1j} + n_{2j}$, $n = \sum n_j$. Let D_j represent the true mean difference in the response variable between treatments 1 and 2 in center j , with d_j denoting an estimate of this quantity; in our simple situation, d_j is the difference of the mean responses in the two treatment groups for patients in center j .

Sensible measures of the overall treatment difference might be viewed as linear combinations of estimates computed from the individual centers; hence, we consider the following family of weighted averages of the within-center estimates:

$$d_w = \sum w_j d_j$$

with

$$\sum w_j = 1.$$

Two specific choices of weights would seem to be most immediately obvious, and historically have been most utilized and the focus of most of the literature discussion on this topic. In the first of these, $w_j \equiv 1/c$, so that the overall treatment difference estimate is the numerical average of the within-center estimates:

$$d_U = \sum d_j / c$$

In the second approach, weights for each center are chosen according to the precision of the within-center estimate, i.e., each w_j is the inverse of the variance of that estimate under an assumption of common variance for the responses, scaled to sum to 1:

$$w_j = (n_{1j}^{-1} + n_{2j}^{-1})^{-1} / \sum (n_{1j}^{-1} + n_{2j}^{-1})^{-1} \quad (1)$$

We refer to d_U as the *unweighted* estimator and d_w [with weights defined as in Eq. (1)] as the *weighted* estimator, and inferences based upon them as unweighted and weighted inferences, respectively.

It should be noted that if within each center the two treatment arms have the same number of patients (a type of balance nearly achieved in many clinical trials because of the randomization stratification mentioned previously), then the weighted estimator simplifies to the difference of the response averages computed over all patients within each treatment arm. In this sense, our choice of terminology might be considered a misnomer from a certain perspective: weighted inference essentially gives equal weight to responses from individual *patients*, while in unweighted inference, patient responses are in effect weighted relative to the sizes of their centers (a patient from a small center having more weight). If in addition the center sizes are the same, then the two parameters we have defined are identical. (Also, the forms of the estimators illustrated here of course lose these simple representations as soon as we deviate from the simple structure we have defined, e.g., if we adjust response for additional covariates, but the key concepts remain largely similar.)

Given the common usage within the pharmaceutical industry of the SAS statistical package,^[17] this issue as it applies to multicenter clinical trials is quite well known to relate to different analysis options in the SAS procedure PROC GLM. It can be noted that an unweighted analysis is obtained using type III sums of squares in PROC GLM when specifying an analysis model—a *computational model* in the sense described by Permutt^[13]—which contains treatment, center, and treatment-by-center interaction, say:

$$y_{ijk} = \mu + T_i + C_j + I_{ij} + e_{ijk} \quad (2)$$

Thus, a t -test constructed from d_U and its estimated standard error provides identical inference to the F -test obtained from the SAS type III ANOVA. A weighted analysis, i.e., one based upon d_w , can be obtained in the same computational model using SAS type II sums of squares. Additionally, inference from a computational ANOVA model that does not contain the interaction term is also based on d_w , albeit with a differently defined error term.

Other approaches to determining weights have been utilized or considered as well. In an approach that is sort of a hybrid of the two most well-known weighting types, it may be specified that a SAS type III analysis will be initially performed, but if the interaction term fails to reach a specified significance threshold then it will be dropped from the model. Thus, this approach can lead to an unweighted or weighted analysis, depending on the results of this interaction pretest (this approach seems to have been considered more in the past, but is rarely used currently). As a further example of a different type of weighting scheme, weights for centers corresponding to expected representation of patients from those centers in a broader population of interest are discussed in Ref. [12].

COMPARISONS OF WEIGHTING SCHEMES

Certainly, we are not restricted to considering only the results from a single analysis of trial data, nor to selecting a single center-weighting scheme. Examining consistency or differences of results across different analyses can be very important in properly interpreting trial results, as we discuss later. Nevertheless, it is conventional in the pharmaceutical industry to prespecify the details of a *primary analysis*, based upon prestudy expectations and assumptions concerning the most appropriate manner of investigating the main trial hypothesis. Though the data themselves may provide valuable clues concerning how they might most appropriately be analyzed, and a number of analyses will generally be performed as part of a thorough examination of the data, results of the primary analysis generally receive most emphasis in initial consideration and interpretation of trial results. Arguments have been put forth in support of the two weighting schemes described earlier for use in primary analyses; these are primarily based upon comparisons of the parameters on which the inferences are based, and upon the precision of the estimates of those parameters.

With σ^2 denoting the common variance of the responses, the variances of the unweighted and weighted estimators are

$$V_U = \sigma^2 \sum \sum n_{ij}^{-1} / c^2$$

$$V_W = \sigma^2 / \left(\sum \left(n_{1j}^{-1} + n_{2j}^{-1} \right)^{-1} \right),$$

respectively.

V_U is always at least as large as V_W , with equality only when all treatment-center combination sample sizes are identical. Illustrations for various levels of center-size imbalance are described in Ref. [9]; it seems fair to say that for magnitudes of imbalance often encountered in clinical trials, the difference between these variances can be substantial. To cite one specific example for illustration,

if most centers in a study have a common sample size, but a quarter of the centers have one-third as many patients as the others, V_U will be 25% larger than V_W .

Variance is of course not the sole basis on which the estimators can be compared, since they generally estimate different quantities (say, D_U and D_W , defined analogously to d_U and d_W), and inferences could thus be viewed as testing different hypotheses. An argument in support of equal center weighting is that in the presence of true treatment-by-center interaction—i.e., an interaction term appears in the *probability model*, again using the terminology of Permutt;^[13] equivalently, the D_j are not all equal—then unweighted inference tests a hypothesis that a priori is clearly defined, namely whether or not the average treatment difference across all centers is zero (or in a slightly broader sense, this quantity at least becomes clearly defined at whatever point we identify the centers that will participate in the study). On the other hand, weighted inference is based on a parameter that is not clearly defined in this sense, i.e., it is not known before the study since it depends on the within-center sample sizes that will be obtained:

$$D_W = \sum \left(n_{1j}^{-1} + n_{2j}^{-1} \right)^{-1} D_j / \sum \left(n_{1j}^{-1} + n_{2j}^{-1} \right)^{-1}$$

In this view, the deviation of this parameter from its unweighted counterpart is considered to be bias.^[11,12] Others have contended that this is not bias and that a weighted approach estimates a validly interpretable quantity.^[5,8,13,14] Senn^[1] has argued that in a practical sense, the parameters on which the two approaches are based will often be quite similar and a true treatment effect will tend to be reflected in either; hence inference based on the more precise of these (weighted) should generally be preferable. Gallo^[9] described how even if interaction were present but center effects were not systematically related to center size, the two approaches would still be based on essentially the same parameter, so that precision would be a sensible basis for decision (and this would of course support weighted inference). Ganju and Mehrotra^[14] discuss that the center sample sizes, and hence the weights in a weighted analysis, are random variables, and that conventional analyses fail to take this into account.

REGULATORY GUIDANCE

Some current regulatory guidance documents have reflected and influenced the evolution of opinions regarding primary analysis models and center-weighting issues. These recommend that in primary analyses, centers should usually be size weighted. Specifically, this is achieved by using analysis models that do not include terms for treatment-by-center interaction; the existence of such interaction is felt to be exploratory in most situations, and the efficiency of the weighted approach would often be

expected to provide the better initial evidence regarding treatment effectiveness. It is acknowledged that reasonable consistency of results across centers and consistency of estimated overall effects based upon different weighting schemes are highly desirable; hence, this should be investigated further in the presence of a positive result from the primary analysis.

Some specific relevant statements from the ICH-E9 document, *Guidance on Statistical Principles for Clinical Trials*,^[18] include:

- “Trials that avoid excessive variation in the numbers of subjects per center and trials that avoid a few very small centers have advantages if it is later found necessary to take into account the heterogeneity of the treatment effect from center to center, because they reduce the differences between different weighted estimates of the treatment effect.”
- “The main treatment effect may be investigated first using a model that allows for center differences, but does not include a term for treatment-by-center interaction. If the treatment effect is homogeneous across centers, the routine inclusion of interaction terms in the model reduces the efficiency of the test for the main effects.”
- “If positive treatment effects are found in a trial with an appreciable number of patients per center, there should generally be an exploration of the heterogeneity of treatment effects across centers, as this may affect the generalizability of the conclusions.”

The CPMP document *Points to Consider on Adjustment for Baseline Covariates*^[2] states:

- “When multicenter trials are stratified by centre, then centre should be adjusted for in the primary analysis regardless of its prognostic value.”
- “The primary model should include only the covariates prespecified in the protocol and no interaction terms. However, treatment by covariate interactions should be explored, as recommended in the ICH-E9 guideline.”

A useful summary of U.S. regulatory perspectives, consistent with the regulatory guidances quoted above, is provided by Anello et al.^[3]

SAMPLE SIZE CONSIDERATIONS

When linear model analyses are used in clinical trials with desired equal allocation to two treatment groups, the total sample size n is conventionally determined using the following formula or some variant:

$$n = 4 \left(z_{1-\alpha/2} + z_{1-\beta} \right)^2 / \Delta^2 \quad (3)$$

where z_p is the p th percentile of a standard normal distribution, and Δ is a standardized treatment difference desired to be detected with power $1 - \beta$ using a one-sided level $\alpha/2$ test (refinements to this formula might be made, for example, to use t -distributions or incorporate other covariates; here, we illustrate only the simple large-sample normal approximation). This is essentially the approach utilized in many commercial sample size software packages.

It has occasionally been stated in the literature that this calculation “assumes that there is no interaction.” This is not really accurate: the validity of the formula is not fully determined by assumed underlying probability models, but rather by the analysis method that will be used and the mechanics of the computations involved. Specifically, this sample size formula depends upon the assumption that the variance of the overall treatment difference estimator is

$$V = 4\sigma^2/n.$$

This in fact is the minimum possible variance based upon n patients. It is the variance of the weighted estimator when there is within-center balance and of the unweighted estimator only if additionally the center sizes are identical (in which case of course the estimators coincide). Thus, it would be more accurate to state that this formula assumes that:

- weighted analysis is being used, or
- center sizes are equal.

If an unweighted analysis is being used, then provided that center sizes are not the same, this sample size calculation will understate the number of patients needed to achieve the desired power. This does not depend on whatever under-lying model is assumed, but rather on the fact that the computational model allows the possibility of interaction. It seems to have been the case historically that studies in which there was no expectation that center sizes would be similar, and in which unweighted primary analyses were specified, were often designed without taking into account the inefficiency that would be introduced by those unequal center sizes, and were thus underpowered. To correct for this, it would be necessary to adjust the sample size calculation according to some measure of center-size imbalance, but of course this is almost always not known in advance. Approaches to approximate the necessary adjustment based on expected levels of center imbalance are described in Refs. [9,19]. This is directly related to the relationship between the unweighted and weighted variances described in a previous section. For example, in the same simple illustrative case we considered earlier, if most centers would be expected to have a common sample size but a quarter of them might be one-third as large, then the result from the conventional formula should be increased by 25% in order to achieve the desired power in an unweighted analysis.

For weighted analyses, this issue is very much minimized: the actual variance and that assumed in Eq. (3) are identical when there is within-center balance, and slight deviation from such balance will generally have little impact. (One caveat involves the possibility of many very small centers. For example, in a center with 20 patients, a treatment differential of 11 vs. 9 will be trivially less efficient than the assumed equal allocation; while in a center with four patients, a 3 vs. 1 treatment split would introduce more relative inefficiency compared to equal allocation. Small within-center randomization block sizes will tend to minimize this concern. Nevertheless, in a trial expected to have many very small centers, it might be considered whether or not the conventional sample size calculation needs to be modified.)

CONSTRUCTION OF COMPOSITE CENTERS

When some centers are very small, a practice of defining artificial “pooled” or “composite” centers is sometimes employed; that is, data from different centers are treated in the analysis as if they came from the same center. A number of small centers may be combined, or one or more small centers may be combined with a larger center. Composites may be constructed to the extent of eliminating empty cells to ensure that treatment effects are estimable in models that contain interaction terms, or so that all observations contribute to treatment effect estimates in models that include center as a main effect. More commonly, this is done to achieve some minimum cell size felt to appropriately limit the influence of individual observations or remove some instability from the analysis. Algorithms for determining the composites are generally specified before unblinding of the trial for final analysis.

In describing the practice of using composite centers, we distinguish this from consideration of covariates that reflect “broader” categories of grouped centers that might be expected to affect response. For example, geographic region might explain allergic or asthmatic responses, centers in less developed areas might enroll patients with a poorer prognosis, experienced staff might have better success using treatment regimens involving complex medical procedures, etc. Accounting for such effects in analysis models can be part of a sensible approach to model determination. The discussion below refers basically to numerical compositing algorithms based upon within-center sample sizes.

The practice of using composite centers seems to have evolved in order to minimize the large variance inflation and data instability that can arise in unweighted analyses when some centers are very small. We have previously described some simple illustrations in which some centers are one-third as large as others; in reality, in many clinical trials the relative imbalance between the largest and smallest centers can be far greater. There may be several

large centers, and then some centers contributing only a handful of patients; allowing estimates from the small centers to have the same weight as the large ones can cause the treatment effect estimates and inferences to be highly sensitive to even moderately unusual response values in the small centers. This instability is reflected in imprecision of the overall estimates. As described by Senn^[1,10] and others, defining composites for unweighted analyses shows concessions toward a weighted approach, that is, this approach moves in a “weighted direction” to decrease the level of imbalance among the (pooled) centers and to lessen the potential influence of very small centers. When using an unweighted analysis with composite centers, both the treatment estimate and its variance generally lie between those of weighted and unweighted analyses based on the original center definitions; see Ref. [11]

There are potential implications of this practice that should be understood. One immediate concern is that, to the extent that any center main effects exist, defining composites will tend to produce an overestimate of the error variance. This effect can be explored in a sensible manner by comparing the error mean square from an analysis using the original center definitions to that from one in which the composite centers are used. Questions of bias introduced by this practice are more subtle and are difficult to summarize briefly, though there would seem to be some potential for bias. This practice certainly changes the weights that centers receive in unweighted analyses: inclusion in a composite decreases the weight given to a center and its patients. If an unweighted approach were advocated on the philosophical grounds that centers must be treated equally and the parameter on which inference is based must be clearly defined, it should be realized that this can no longer be claimed when composites are utilized. In the presence of interaction, the parameter that is the basis for inference depends on center sizes in the same manner as weighted analyses, albeit to a lesser extent (unweighted analysis using composites has been described as weighted *within* composites, but unweighted *across* them^[11,12]). Unlike weighted analyses, it may not even be possible to claim that centers of similar sizes are weighted comparably in unweighted analyses using composites; for example, one center may be right at the maximum size limit for inclusion in a composite and thus substantially downweighted, while a center with a single additional patient might stand alone and receive full weight.

It seems to be the case that composites are sometimes used for primary weighted analyses as well (i.e., models without the interaction term). There is likely some residual usage of this practice left over from the days when unweighted primary analyses were more common, though there is far less motivation for it. The issues are much different for weighted analyses, in which composites are generally not needed because the influence of small centers is directly limited by their sizes. The CPMP document^[2] discourages use of the practice: “... pooling small centers to

form one center of size comparable to that of other centers has little or no scientific justification.”

A special case that might be considered further involves “empty cells” resulting from centers in which there is a treatment to which no patients have been assigned. In the ANOVA model we used, such centers will not contribute to the treatment difference estimate (they may affect other aspects of the analysis, e.g., the error term). Perhaps they should not contribute, if we really believe center to be strongly predictive in a main-effect sense. Nevertheless, there is understandable motivation to have all primary endpoint data contribute to the treatment effect estimate; pooling can be one way to do this, and a small amount of pooling should generally not be expected to impair weighted analyses. If many centers contributed empty cells, then the analysis model likely could not accommodate main-effect adjustment for center, and the interpretation of the analysis would depend on the reasonableness of this assumption.

CENTER WEIGHTING IN RANDOM-EFFECT MODELS

As mentioned previously, random-effect models, or mixed models, present an intriguing alternative to fixed-effect models for multicenter trial analyses. In these models, treatment-by-center interaction effects, and perhaps center effects as well, are considered to be random variables. Indeed, there are aspects of this situation that often seem much more logically consistent with a random-effect approach. For example, trial results are normally viewed as having relevance in a broader population of settings than those actually used in the trial (though perhaps not with effects identical to those in the centers selected for clinical trials). Also, inconsistency of effect across centers may tend to make one less certain that a treatment effect has been characterized accurately, since it would then be reasonable to consider whether the results might have been different had different centers been used, and random-effect models handle this in a very natural manner.

These models have received some attention in the literature (e.g., Refs. [1,10,15,16,20–22]), and can be considered an additional option in the pharmaceutical industry for primary analyses, but they have by no means superseded the use of fixed-effect models. Random-effects models are considered to be a “good fit” more often for trials in which there are a large number of centers each contributing only a small proportion of the total number of patients in the trial. It has frequently been stated, and is certainly true, that centers used in clinical trials are not selected by any type of random mechanism from some population of potential sites. On the contrary, they are often selected precisely because of attributes in which they differ from other sites; e.g., the investigators possess some special expertise, the center has experience in participating in clinical

trials, it can enroll the desired number of patients in a timely manner, etc. Thus, while presumably there is some continuity principle operating so that results from clinical trials would provide valuable information as to how treatments will work in other settings, it is usually difficult to describe the population from which the centers used in a clinical trial could be expected to behave as a random sample. While there is currently an increased body of opinion that random-effect models would provide more appropriate inferences in multicenter clinical trials, until relatively recently the historical consensus in the pharmaceutical industry, at least as evidenced by selection of primary analysis models, seems to have been much as described by Fleiss,^[20] namely that while neither fixed nor random approaches seem uniformly a perfect fit, clinical trial sites seem “more fixed than random.”

Though there are fundamental differences between the assumptions made in fixed and random-effect models that prevent simple comparisons, we can address the weights that centers receive in random-effect analyses, and it is instructive to compare these to the fixed-effect weights described in previous sections. For a model of the form of Eq. (2), we now view C_j and I_{ij} as independent zero-mean normal random variables with variances, σ_C^2 and σ_I^2 , respectively (though under equal within-center treatment allocation, or something close to it, the choice of C_j as fixed or random will usually have minimal impact on the analysis).

A mixed model analysis (for example, restricted maximum likelihood, the default method in SAS PROC MIXED) can be viewed as determining weights that minimize the variance of the treatment difference estimate, using variance components that are simultaneously estimated. Further details are provided in Ref. [9], but in summary, these center weights satisfy

$$w_j^* \sim n_j / (Rn_j + 1 - R)$$

(i.e., w_j^* is proportional to this quantity, and the $\{w_j^*\}$ sum to 1), where R is the following ratio:

$$R = s_I^2 / (s_I^2 + s^2)$$

with s_I^2 and s^2 denoting the estimates of σ_I^2 and σ^2 , respectively.

Weights given to centers in this mixed model analysis will always lie between those they would have received in weighted and unweighted fixed-effect analyses. Note that as R gets small, the weights w_j^* approach those of a weighted analysis, which intuitively seems sensible, since if the data suggest that interaction is negligible, then there is no ambiguity in the main-effect parameter being estimated, and size-weighted estimates are most efficient. As R approaches 1 (i.e., s^2 is small relative to s_I^2), we approach equal weighting. Though perhaps less intuitive, and certainly less realistic, if “patient” essentially provides no

information beyond its center and treatment, then “center” is the only experimental unit, and it should then seem sensible to average equally over levels of this factor.

One might compute these weights to try to validate in some sense the choice between the common types of fixed-effect weightings—there is nothing that prevents one from applying these random-effect type weights in a fixed-effect model (in fact, an interesting discussion of attributes of this weighting scheme in an underlying fixed-effect framework is presented in Ref. [13]). Directly comparing fixed and random-effect model inferences is more problematic, but there are some tendencies we can note. The variance of the mixed model estimate d_M determined using weights $\{w_j^*\}$ can be seen to have two components:

$$\text{var}(d_M) = 2\sigma_i^2 \sum w_j^{*2} + 2\sigma^2 \sum w_j^{*2} / n_j$$

Perhaps not surprisingly, the first component will tend to be inversely related to the number of centers, and the second to the number of patients. The coefficient of the second component is always between the coefficients of σ^2 in weighted and unweighted fixed-effect models; hence, the variance of the mixed model estimate will normally be at least as large as in a weighted analysis. The first term inflates the variance further for any apparent inconsistency of effect across centers, which as alluded to previously, should seem reasonable: one should have more confidence that a suggested effect is real if it is consistent across centers, because then the outcome would seem less likely to have been influenced by the selection of centers that actually participated in the study.

If the interaction variance component is estimated to be zero, then the first term in the estimated variance disappears. The center weights will exactly be those of a weighted fixed-effect analysis, and inferences will be nearly identical—the estimate will be the same, though the error term and d.f. might differ slightly (if our assumption of within-center balance is violated, the weighted and mixed model estimates will tend to be very slightly different). Roughly, this will occur when the conventional ANOVA F -ratio for interaction is < 1 , corresponding to an interaction p -value of at least 0.50–0.60, with the exact threshold depending on the size of the study. If the interaction estimate is nonzero (again, roughly when the ANOVA p -value for interaction < 0.50), the mixed model variance will be larger than the weighted fixed-effect variance, and possibly much larger, depending on the magnitude of the interaction signal and the number of centers.

Rightly or wrongly, this may hinder broader use of random-effect analyses in the pharmaceutical industry, since current conventions accept weighted fixed-effects analyses, and the tendency when using random-effect models will be toward less significant results, even for interactions that do not approach conventional standards of significance. Use of a large number of centers would seem

to be imperative in order to stabilize the corresponding variance component if there were a signal of interaction. On the other hand, this approach could decrease current concerns about thresholds for significant interaction that might be interpreted as invalidating or shedding doubt on overall treatment comparisons: in mixed models, interaction is handled in a systematic manner, with lower or higher evidence of interaction translating naturally into a more or less significant outcome.

One other practical problem with implementing mixed models would seem to involve trial design: sample size estimates will often be highly dependent on hypothesized interaction variances, for which it will often be difficult to determine in advance a dependable value. Also, it follows directly from the discussion above that sample sizes needed to achieve a particular power will usually be larger for random-effect models that assume a positive interaction variance compared to conventional fixed-effect sample size calculations. In fact, power will not be solely a function of the number of patients, but of the number of centers and distribution of patients across centers as well.

EXTENSIONS TO NON-NORMAL DATA

The discussion here has focused on ANOVA models for normally distributed data. The issues are of course relevant for other data structures as well, though these have not received the same level of detailed attention in the literature. Binary or categorical outcomes, longitudinal data, or time-to-event data are just a few examples that are analyzed using different methods to which the principles and tendencies illustrated above apply to some extent. (A thorough investigation of these issues for multicenter trials with binary responses is provided in Ref. [23].)

Primary analyses that can be viewed as being based on equal-center weighting (analogous to the SAS type III approach) have probably been considered and performed far less frequently for alternative data structures. In most cases, there is no technical reason why they could not be; for example, a time-to-event analysis utilizing a proportional hazard approach could estimate the log hazard ratio within each center and combine these using Type III weighting. More frequently than for normal data, other methods may not even account for center at all, particularly when most centers are quite small and it is plausible that center does not strongly predict outcome (see e.g., ICH-E9:[18] “In some trials, for example, some large mortality trials with very few subjects per center, there may be no reason to expect the centers to have any influence on the primary or secondary variables because they are unlikely to represent influences of clinical importance. In other trials, it may be recognized from the start that the limited number of subjects per center will make it impracticable to include the center effects in the statistical model. In these

cases, it is not considered appropriate to include a term for center in the model.”). So long as within-center treatment allocation is similar across centers, analyses that ignore center can generally be interpreted as providing similar weight to each patient, thus giving weight to centers that is related to their size.

Some analysis methods allow centers to define strata. For example, binary data might be analyzed using a Cochran-Mantel-Haenszel analysis that is stratified by center; time-to-event data might be analyzed using stratified logrank tests or stratified Cox proportional hazard models. In such stratified analyses, it can again be viewed that appropriately scaled treatment effects are computed within each stratum and then combined based upon their (inverse) precision—in other words, size-weighted analyses. It seems as if equal center weighting in primary analysis models has most often been considered for normal data methods. For other methods and data structures, random-effect models would also have some potential to modify center weights similarly as was illustrated above.

CONCLUSIONS

In recent years, it has become more standard practice for primary analyses that use fixed-effects models in multicenter clinical trials to utilize methods that can be viewed as combining center-specific estimates according to their precision, i.e., more precise within-center estimates receive more weight. Precision will often be directly related to the number of patients enrolled at a center. This is reflected in current regulatory guidance documents. The advantage of this weighted approach is that it is in general a highly efficient framework within which one can combine the within-center estimates, similar to the way many statistical methods in various contexts combine information on an inverse precision-related basis. In normal linear models analyses, this weighting is usually achieved by using an ANOVA model which does not contain a term for treatment-by-center interaction. It is true that the parameter on which inference is based is not necessarily the same as that in an analysis in which within-center estimates are weighted equally. Nevertheless, the main question of practical interest—whether there is evidence of treatment effectiveness—will generally be reflected in any reasonable weighting choice, and the efficiency of the size-weighted approach will often be best able to provide a good initial signal as to whether such evidence exists.

This by no means implies that analyses that use other weightings should not also be produced and considered in full investigation of trial results. Whether or not effects are similar across centers can be important in judging whether the magnitude of a treatment effect has been adequately characterized, and whether there are other population characteristics or treatment

administration details that are relevant to understanding how well patients respond to the treatment. ICH-E9^[18] recommends: “If positive treatment effects are found in a trial with appreciable numbers of subjects per center, there should generally be an exploration of the heterogeneity of treatment effects across centers, as this may affect the generalizability of the conclusions.” Such interaction could cause estimated effects based upon different weightings to “aim” at noticeably different targets if the treatment effects are systematically related to center size. For example, if a size-weighted analysis suggests a larger treatment effect than an unweighted analysis, then there must be some apparent positive correlation between effect and center size, i.e., a tendency toward larger effects in larger centers, which may point in a direction for further investigation. In general, examining how analyses seem to be affected by different center weightings can be a useful diagnostic tool assisting in most fully interpreting and understanding trial results.

Clinical Data Management

Terri Madison and Marianne Plaunt

STATPROBE, Ann Arbor, Michigan, U.S.A.

Abstract

Clinical data management (CDM) is the process of collecting and validating clinical information with the goal of converting it into an electronic format to answer research questions and to preserve it for future scientific investigation. The objective of this entry is to present key data management concepts and to provide a brief overview of CDM processes.

INTRODUCTION

Clinical data management (CDM) is the process of collecting and validating clinical information with the goal of converting it into an electronic format to answer research questions and to preserve it for future scientific investigation. As computerized data increasingly become the basis for scientific research, CDM continues to grow as a discipline. Reporting accurate and reliable study results is dependent on the ability to efficiently access and accurately manipulate information stored in computer files. The collection of files can quickly become unmanageable without a systematic approach, and the CDM discipline provides a practical framework for creating well-documented data of consistent quality, permitting research projects to proceed quickly and easily.^[1]

The objective of this article is to present key data management concepts and to provide a brief overview of CDM processes. The article begins with the identification of current regulations and guidance documents with relevance to CDM, highlighting the specific parts of these regulations that directly apply to CDM practices. This section is followed by a discussion of CDM processes, beginning with case report form (CRF) design and ending with database closure. In this section, key principles for each process are provided, followed by a process overview. The article concludes with an overview of CDM systems.

REGULATIONS AND GUIDANCES RELEVANT TO CLINICAL DATA MANAGEMENT

Most CDM practices are not specifically addressed in existing regulations and guidance documents. The regulations and guidance documents currently in place that apply to CDM are identified in this section. The objective of this section is to describe the purpose and scope of each relevant regulation or guidance, highlighting the specific parts of each regulation or guidance that directly address CDM practices.

21 CFR Part 11—Electronic Records, Electronic Signatures

These regulations describe the criteria under which the Food and Drug Administration (FDA) will consider electronic records and signatures to be generally equivalent to paper records and handwritten signatures, and applies to any records required by FDA regulation or submitted to FDA under agency regulations.^[2] The requirements for audit trail systems are also covered in 21 CFR Part 11. A large portion of 21 CFR Part 11 has direct relevance to CDM. Persons who create, modify, maintain, or transmit electronic records are required to have procedures in place that ensure the authenticity and integrity of these records. Systems must ensure electronic records are accurately and reliably retained, must be able to discern invalid or altered records, and must track revisions to electronic records such that previously recorded information is not obscured. Closed systems must ensure access only by authorized individuals, and open systems must use additional measures such as document encryption to ensure authenticity and integrity. Systems must also have the ability to generate documentation suitable for agency inspection to verify that these requirements have been met. Persons responsible for the records must have the necessary education, training, and experience to perform the assigned tasks. Written procedures must exist for actions relating to electronic records and electronic signatures. Electronic signatures must contain associated information that indicate authenticity, must be certified to the agency as a legally binding equivalent of a handwritten signature, and must be linked to their respective electronic records to ensure signatures cannot be transferred to falsify an electronic record.

21 CFR Part 312—Investigational New Drug Application

Part 312 contains the procedures and requirements that govern the use of investigational new drugs, including the

procedures and requirements for submitting an investigational new drug (IND) to the agency.^[2] Part 312.62(b) has direct relevance to CDM, and covers requirements for investigator recordkeeping and record retention. Specifically, investigators are required to keep adequate case histories that record all data pertinent to the investigation on each individual administered an investigational drug or used as a control in the investigation. These case histories include the CRFs and supporting data.

21 CFR Part 314—Applications for Food and Drug Administration Approval to Market a New Drug

This part establishes procedures and requirements for the submission of applications and abbreviated applications to the agency, and for the agency to review the application.^[2] It also applies to application amendments, supplements, and post-marketing reports. Parts 314.50(f)(1) and (f)(2) pertain to the inclusion of CRFs and tabulations in an application, and therefore directly apply to CDM. Full case report tabulations are required from each adequate and well-controlled study (Phase 2 and Phase 3 studies) as well as from clinical pharmacology studies (Phase 1 studies), unless prior agreement was obtained from the agency. Safety data tabulations are required from other clinical studies. Applications must also contain copies of individual CRFs for each patient who died during a clinical study or who withdrew prematurely from the study due to an adverse event.

Bioresearch Monitoring—Compliance Program Guidance Manual

This guidance provides specific and uniform instruction for agency inspections of clinical investigators, sponsors, laboratories, and institutional review boards as part of the agency compliance program to assure the quality and integrity of data submitted to the FDA.^[3] Program 7348.810 is directly applicable to CDM, and governs sponsors, contract research organizations, and monitors. The guidance provides for establishment inspections of organizations responsible for data collection and handling, and includes the review of data tabulations for each subject, the review of the sponsor's data collection and handling standard operations procedures to assure the integrity of the data collected, and the verification that procedures were followed. The guidance also covers automated entry of clinical data to determine compliance with 21 CFR Part 11.

Guidance for Industry—Computerized Systems Used in Clinical Trials

This guidance provides additional detail regarding the principles to be followed when computerized systems are

used to create, modify, maintain, archive, retrieve, or transmit clinical data intended for submission to the agency.^[4] The guidance also addresses requirements similar to those in 21 CFR Part 11. The primary focus of this guidance is computerized systems used at clinical sites to collect data; however, the principles may also be appropriate for computerized systems at sponsors, contract research organizations, and CDM centers. Computerized medical devices and diagnostic laboratory instruments are outside the scope of this guidance. As this guidance contains many key principles with direct relevance to CDM, specific principles set forth in this guidance are highlighted in the section “CDM Processes” of this article.

International Conference on Harmonization—Consolidated Guideline for Good Clinical Practice

This document sets forth a tripartite standard for the conduct of clinical trials, and covers preparation, monitoring, reporting, and archiving of clinical trials.^[5] Section 5.5 pertains to trial management, data handling, and recordkeeping, and requires that: (1) appropriately qualified individuals handle and verify the data, (2) electronic data-handling systems used are validated, have corresponding standard operating procedures (SOPs), maintain an audit trail, prevent unauthorized access, maintain adequate data backup, and safeguard the blinding, and (3) original data are maintained in situations where data are transformed during processing. Section 8 sets forth the requirements for signed, dated, and completed CRFs and documentation of CRF corrections as essential trial documents that must be maintained.

CLINICAL DATA MANAGEMENT PROCESSES

Case Report Form Design

21 CFR Part 12 requires the investigator to record all data pertinent to the investigation for each individual administered an investigational drug or used as a control in the investigation.^[2] The study protocol delineates the observations required to demonstrate the safety and efficacy of an investigational product; the CRF is the instrument developed to systematically record these observations.

Many factors need to be considered in designing the CRF. Some of the key principles to consider are:

1. The CRF should be designed to capture all data required per the protocol.
2. The CRF should be designed to collect data elements in standardized format.^[6] Standardization facilitates the aggregation of data across clinical investigations in a drug development program, promotes consistency in data reported to regulatory agencies, and

decreases the potential for bias from recording data using dissimilar collection methods.

3. Data elements should be captured on the CRF in a fashion that ensures the data are suitable for summarization and analysis. Numeric data or predefined checkboxes of possible outcomes are more useful than open text. If necessary, text may be recorded in a way that facilitates the assignment of codes to similar responses so that textual data can be summarized.
4. Data elements planned to be transcribed to the CRF from source documents should be organized and formatted on the CRF to reduce the possibility of transcription error and to facilitate subsequent comparison to source documents. Units, format, and level of precision on the CRF should be similar to those of the source document.
5. Ease of completion for the investigator and study coordinator is key to accurate and timely CRF completion. Instructions for filling out the CRF should be prominently displayed. Related data elements should be clustered together and should flow similarly to patterns of medical record documentation. Checkboxes and areas to record responses should provide adequate space to record the anticipated results. Predefined response choices should be used to minimize unanticipated responses or ambiguous data. Adherence to these principles will also facilitate the review performed by clinical research associates (CRAs) and data coordinators of the completed CRF.
6. Redundant data elements within the CRF should be avoided, and unnecessary data should not be collected.

The CRF design process begins with a careful review of the protocol and selection of applicable CRF standards, if available.^[6] A protocol-specific draft CRF is developed, often in consultation with the study manager to ensure efficacy and that the safety data elements will accurately capture the intended data. The draft CRF is typically reviewed by the CRA, data coordinator, biostatistician, and study manager prior to finalization. After the CRF and instructions have been finalized, the CRF and associated instructions are assembled in patient-specific booklets or binders, printed, and distributed to investigators. The CRF is typically printed on two- part or three-part NCR paper, with the original (and first NCR copy, if present) for the sponsor and the last copy to be retained by the investigator. The CRF should be made available to investigators prior to enrollment of the first subject.

Electronic data collection system, such as a web-based electronic data capture system or an interactive voice response system (IVRS), are increasingly being used in clinical investigations. Data may be collected directly into the electronic system, may be recorded on source documents such as medical record progress notes and later

input into the electronic system, or may be recorded on protocol-specific worksheets developed specifically for the electronic data capture setting to be subsequently entered into the electronic system. In all of these situations, a CRF is not developed; however, most of the CRF design principles described in this section apply to the design of worksheets or data entry screens in an electronic data collection setting.

A more thorough discussion of CRF design principles and processes can be found in Ref. [6].

Database Design

The storage of data from clinical investigations must preserve the integrity of the data while ensuring efficiency throughout various data-handling processes. This section discusses key principles for developing and validating protocol-specific databases. A discussion of various commercially available types of data management software and a comparison of the advantages and disadvantages of each are provided in the section "Clinical Data Management Systems."

The database structure is driven by the data elements collected on the CRF. The use of standard templates, where available, to build protocol-specific database modules and format libraries (data dictionaries) enhances the efficiency of the database development process and facilitates subsequent aggregation of the data. Codes should be assigned to nonnumeric data to allow efficient data entry and retrieval into standard data tabulations and summary reports.^[7] If data are transformed, the original data recorded on the CRF must also be stored in the database.

The steps in developing a protocol-specific database are illustrated in Fig. 1. The process begins with the identification of applicable standard templates. Once a draft structure is available, team members such as the programmer and biostatistician review the structure to ensure the storage format of data elements supports data tabulation and summarization. Test data should be developed to validate the database and associated structures. The validation process should ensure that all variables are storing data as intended, that derivations are working accurately, and that the audit trail captures data revisions as required by 21 CFR Part 11. Additionally, test data should attempt to "stress" the system to ensure data storage works in situations of unanticipated responses or larger than expected amounts of data. After the database has been thoroughly validated and approved by the project team, the database is put into production and is ready to accept actual data from the clinical investigation.

Data-Handling Standards

Data-handling standards are created to ensure that data are reliable, complete, and accurate. Data handling includes receiving, entering, cleaning, coding, reconciliation, and

Fig. 1 Database development process

transferring of data. The data-handling process is illustrated in Fig. 2.

Prior to entering data, written procedures that describe data processing steps and the required quality level should be developed. A data management plan (DMP) is developed to document the data processing guidelines to be followed for a specific study. The DMP should describe CRF receipt and tracking processes, CRF review and query guidelines, specifications for computer edit check programs, data entry guidelines, quality assurance methods/audit plan for the study, coding processes and the coding dictionaries to be used, data collection and handling processes for electronic data from external sources, and serious adverse event (SAE) reconciliation processes. The DMP should provide enough specificity to reproduce the database from source documentation.

The data entry process utilized should address the data quality needs of the investigation. FDA and ICH regulations do not stipulate a specific data entry process. The skill level of the resource, the time available, the overall cost-effectiveness, and the impact of data errors on study conclusions should all contribute to the choice of a data entry process. Double data entry is helpful where data are

subject to frequent, random, keystroke errors or where a random error would be likely to impact the analyses. There are two main types of double data entry: (1) independent double data entry with a third person compare, where two persons independently enter the same data, and a third person resolves any discrepancies between the two entries and (2) double data entry with blind or interactive verification, where two persons enter the data independently but sequentially, and discrepancies are resolved during the second entry pass. A single data entry process, with or without visual verification, may also be appropriate for certain investigations. Imaging and optical character recognition (OCR) processes may be used to populate a database. This process automates the first entry, and is followed by manual verification of specific fields that did not meet the established confidence criteria.

In studies where electronic data collection systems are used, a typical process entails a single entry of the data into a centralized database through a web browser or utilizing a client/server model by site personnel, with periodic transmissions to the central database. The data are subsequently verified using source documents. Other forms of electronic data capture include IVRS and direct data capture

Fig. 2 Data management process traditional data collection

devices such as electronic patient diaries. If electronic data collection methods are utilized, validation of the data collection application is especially critical. In electronic data collection, data directly input into the system may be the only source data available, and thus the system must be demonstrated to perform reliably in collecting the data.

Incorporation of electronically collected data into the protocol-specific database presents several unique steps to the data-handling process. Key variables (data that uniquely identify each record) must be identified and included in the data transfer, as key variables are used to merge external data with CRF data (if applicable) in the protocol-specific database. Variables that will be transmitted from electronic data sources to be loaded into the protocol-specific database should be identified, and variable attributes such as length, type, level of precision, and the use of special characters should be defined. Variables to be transferred, record format, and file format should be agreed upon in writing prior to the first data transmission. A file naming convention and inclusion of information such as file origin, date created, date sent, and number of records should be followed to ensure proper identification and version control for each transmission. Ideally, test data from electronic data capture systems should be made available to use during database development and validation. Successful generation, transmittal, receipt, loading, and screening of the test data validate the data transmittal process.

Data Validation

Data validation is the collection of activities used to ensure the validity and accuracy of the data. Activities for data validation may include manual review of the data; however,

programmatic validation provides high consistency and lower error rates. Procedures should be neutral and should not suggest bias or lead responses. The objectives of data validation are:

- Ensuring data entered into a computer-readable file are consistent with the source data.
- Checking that character and numeric variables contain only valid values.
- Checking for and eliminating duplicate data entries.
- Checking for missing values for variables where complete data are necessary.
- Checking for uniqueness of certain values, such as subject identification.
- Checking for invalid date values and invalid date sequences.
- Verifying that complex multiframe (or cross panel) rules have been followed.^[9]

Data may be changed as a result of data validation procedures. Both the investigator site and the data center must retain a record of all changes to the data. Data changes must be recorded and documented by a fax or original site signature acknowledging the new data; this is usually accomplished using a query or data clarification form. Under certain circumstances, data conventions may specify data that can be modified without a site's acknowledgement. These are typically referred to as "obvious changes" or "level 1" changes, and may include correction of obvious spelling errors, unit conversions, and completion of missing identifiers. As required in 21 CFR Part 11, an audit trail should reflect all deletions, updates, or additions to data after initial entry. The audit trail should also

reflect the date and time of the change, the user making the change, and the reason for the change.

Data validation processes in an electronic data capture setting differ from those in a paper-based setting. Many of the objectives of data validation in a traditional paper-based system require postentry processes; an advantage of electronic data capture systems, if designed well, is that most data validation objectives can be accomplished within the system at the point of data collection. Data validation procedures for electronically captured data need to include conventions for handling partial data transfers and procedures for checking for duplicate demographic details and results. Additionally, processes for identification and resolution of discrepancies between electronically captured data and CRF data, where redundancies in some of the data captured from each source may be common, should be defined in the DMP.

Closing a Database

At the end of the data management process, after all data have been received, entered, or transferred into the database, and validated, the database is ready to be closed and prepared for analysis. Closing a database implies no further additions or revisions to the data will be made, and access will be restricted to “read-only” status. Some CDM centers further differentiate between a “closed” and a “locked” database, where “closed” implies that all CDM tasks have been completed. Project team review and additional derivations such as patient evaluability are subsequently completed prior to “locking” the database. Unblinding of treatment assignment is typically performed after the database has been locked,^[8] although exceptions where unblinding occurs just prior to lock have been noted.

Prior to closing a database, the following steps should be completed:

- All data have been received and entered (or transferred) into the clinical database.
- All data validation procedures have been performed, and resulting data discrepancies have either been resolved or deemed to be not resolvable.
- Derived variables have all been successfully populated, including variables derived from coding thesauri such as MedDRA^[10] or WHODrug.^[11]
- An audit of the data has been conducted that certifies the overall quality of the database to meet a preestablished quantitative metric.

Developing a checklist of steps to complete prior to database closure helps ensure a systematic approach and completion of necessary steps. Each step on the database closure checklist is systematically checked to ensure completion, and the process culminates with the database audit. The audit, performed by persons independent of the CDM project team, typically involves the selection of a statistically appropriate random sample of the data to estimate overall quality, with verification of the stored data against the source document and assurance that data-handling procedures were followed for data included in the random sample. If the database audit demonstrates that quality acceptance criteria have been met, the database is closed.

Currently, federal regulations and guidelines do not stipulate an acceptance level for the quality of clinical investigation data. The Institute of Medicine defines data quality as “data that support conclusions and interpretations equivalent to those derived from error-free data.”^[12] Acceptance rates in current use in the industry vary widely;

Table 1 Data Management Software Applications

Software	Research uses	Advantages	Disadvantages
Spreadsheet • MS Excel • Lotus 123	Data entry into a matrix of columns and rows; simple transformation, descriptions, sorting and reporting	• Easy entry of raw data • Derived values may be programmed • Summary descriptive statistics and frequency distributions • Facilitates logic checks through sorting and calculated fields	• Missing value codes cannot be ignored when calculating descriptive statistics • Slow speed when there are many observations • Absence of functions for editing, accessing, and analyzing the data
Database management • Oracle • MS Access • Sybase • SQL Server	Data entry with interactive editing and greater ability to manipulate, access and report the data	• Suitable for studies with large numbers of variables and observations • Interactive editing • Automatic logic checks • Allows duplicate data entry	• Require experienced programmer for system customization • Modifications due to changes in data collection forms may be difficult
Statistical/graphics • BMDP • SAS-PC • SPSS-PC • S-plus • STATA	In addition to some of the above features: statistical analysis and graphics	• Data entry directly into a statistical analysis program • Bypass the need to transfer data from spreadsheet or database management system for statistical analysis	• Limited editing and data management functions

however, current practice recommends an acceptance error rate between 0.01% and 1%, and best practice recommends an acceptance error rate < 0.01% (excluding comments).^[8]

CLINICAL DATA MANAGEMENT SYSTEMS

A CDM system is defined as a set of systematic CDM activities and procedures related to acquiring, manipulating, documenting, and storing research data in a computerized environment. A CDM system is composed of interrelated CDM processes, such as data collection, data entry, data validation, and backup.

One of three main classes of software is usually chosen for data management: spreadsheet programs, database management systems (relational databases), and statistical/graphics programs.^[7] Research applications of these software systems are shown in Table 1. The choice of software is in part driven by the nature of the investigation. An efficient approach is to choose the simplest alternative, considering the resources available for the project such as personnel, time, and computing equipment.

As required by 21 CFR Part 11 and ICH GCP guidelines, CDM systems are required to prevent unauthorized access to the data, and must ensure the authenticity of the stored data. Regulatory requirements for CDM systems are described in detail in the section "Regulations and Guidances Relevant to Clinical Data Management."

CONCLUSION

CDM is a broad and growing discipline that requires knowledge and expertise in information technology and systems, programming practices, regulations, and quality practices, as well as familiarity with medical terminology and clinical care to ensure data are appropriately collected, reviewed for consistency, and resolved within the context of clinical appropriateness. The tremendous growth in the scale and number of research investigations has created a need for knowledgeable clinical data coordinators. As the biopharmaceutical and medical device industry and regulatory bodies increasingly rely on computerized clinical trial data for critical decision making, it is essential that clinical data coordinators pursue additional training in this discipline to ensure the highest accuracy and integrity of these data. The development and implementation of a standardized CDM training program would greatly facilitate this objective.

Clinical Endpoint

Sofia Paul

Eli Lilly and Company, Carmel, Indiana, U.S.A.

Abstract

Clinical endpoint is a clear, hard, clinically relevant outcome measure that is affected by the intervention under investigation and that can be objectively assessed. This entry works to illuminate several types of endpoints in clinical trials and addresses key medical and statistical issues.

INTRODUCTION

A clinical trial is an experiment performed by a health care organization or professional to evaluate the effect of an intervention or treatment against a control in a clinical environment. It is a prospective study to identify outcome measures that are influenced by the intervention. A clinical trial is designed to maintain health, prevent diseases, or treat diseased subjects. The safety, efficacy, pharmacological, pharmacokinetic, quality-of-life, health economics, or biochemical effects are measured in a clinical trial.

There are two different types of clinical trials, confirmatory and exploratory trials.^[1] In an exploratory trial, the choice of hypothesis is data dependent, even though this study may have clear objectives. These trials explore the doses of subsequent studies and provide a basis for a confirmatory study design. A confirmatory trial is a well-controlled study in which the hypothesis of interest is predefined and is intended to provide hard evidence in support of claims that have clinical benefits. A confirmatory trial is less vulnerable to bias and more robust. Atherosclerotic cardiovascular disease (myocardial infarction and cardiovascular death) is the leading cause of death in women in the United States and in most developed countries worldwide. An example of a confirmatory cardiovascular clinical trial would be a multicenter, double-blind, placebo-controlled, randomized, parallel study of 10,000 patients to test whether a new treatment compared with placebo reduces the incidence of the combined endpoint of coronary death and nonfatal myocardial infarction in postmenopausal women at risk for coronary events.

CLINICAL TRIAL

Objective

A clinical trial generally consists of two different sets of objectives: primary and secondary. The primary objective

is the most important question or the hypothesis an investigator desires to answer definitively at the end of the study and that drives the size and the power of the trial. The hypothesis of interest in a confirmatory trial is directly related to the primary objective. The secondary objective(s) answer other related or unrelated questions based on the efficacy or safety of the intervention. In our earlier example, the primary objective is to compare the effect of the treatment with placebo on the coronary death and nonfatal myocardial infarction. There could be several secondary objectives, e.g., to test the effect of the treatment on myocardial revascularization, stroke, all-cause mortality, all-cause hospitalization, breast cancer, fractures, and long-term safety.

Outcome Measures

An outcome measure is a direct or indirect measurement of a clinical effect in a single, adequate, well-controlled clinical trial (it can be double blind or open label) to obtain an effective claim regarding the intervention under investigation. The goal of the clinical trial is to assess the effect of the treatment on these outcome measures. In the primary objective there is generally one primary outcome, which is used to test whether the intervention is superior to a comparative agent (placebo control or active) or that it is not clinically inferior (equivalence) to a comparative agent (placebo control or active). Outcome measures should be selected prospectively.

Primary Endpoint

The primary endpoint is an outcome measure that is related to, and selected based on, the primary objective of the study. The size of the trial is based on the primary objective of the study and the primary endpoints. The primary endpoint in our earlier example is the combined endpoint of coronary death and nonfatal myocardial infarction.

Secondary Endpoints

Secondary endpoints are other outcome measures that may or may not be related to the primary objective of the study. Secondary variables are related to secondary objectives. They support the primary variables of the study. Secondary variables can be a “time to an event,” “incidence rate of an event,” or continuous variables related to efficacy or safety. In the previous example, the secondary endpoints are myocardial revascularization, stroke, all-cause mortality, all-cause hospitalization, breast cancer, fractures, and safety laboratory parameters.

Primary and secondary endpoints are intimately related to the primary and secondary hypotheses. These endpoints can be clinical, surrogate, economic, global, etc. To achieve the study objective, the design should be chosen adequately to reflect the objectives, appropriate primary, secondary, and global variables will be considered that will answer the objectives.

Clinical Endpoint

A clinical trial endpoint is defined as a measure that allows us to decide whether the null hypothesis of clinical trial should be accepted or rejected. Thus, a clinical endpoint is a clear, hard, appropriate outcome that can be objectively assessed, not depending on the judgment of an individual, especially the investigator. Nonfatal myocardial infarction is an example of an objective endpoint, in contrast to a subjective endpoint, e.g., relief of symptoms or severity of symptoms.

Surrogate Endpoint

An endpoint that provides an indirect measurement of a clinical effect when measuring outcome directly is not feasible or practical (because of the requirement of large sample size, long duration, and cost) is called a surrogate endpoint.^[2] A surrogate endpoint is a measure of effect of a certain treatment that may correlate with a clinical endpoint. Changes induced by a treatment on surrogate variables are expected to reflect changes in a clinical endpoint. It should be noted that NIH defines surrogate endpoint as a biomarker intended to substitute for a clinical endpoint. Generally, these endpoints are continuous response variables that can be substituted for the clinical outcomes. For example, surrogate variables might include biochemical markers of cardiovascular disease such as low-density lipoprotein cholesterol, total cholesterol instead of myocardial infarction; spine bone mineral density instead of incidence of vertebral fractures, and CD4 count and viral load effects for the effect on HIV infection.

Economic Endpoint

In recent clinical trials, the evaluation of a subject's health status data has become increasingly important. Several

measurements regarding a subject's use of health care, cost of hospitalization, etc. are considered as economic endpoints. The quality-of-life scores based on a subject's performance, daily activity, mood, etc. (defined by the World Health Organization) are subjective measures of health status. The overall score from these measurements can be analyzed for treatment comparison.

Global Assessment Variables

Global assessment variables measure the overall safety and efficacy of an intervention. These are generally based on rating scales. An idea of the risk–benefit profile of an intervention can be assessed from these variables. It helps the investigative physician to balance the safety and efficacy of the intervention and decide on treating subjects by weighing its risk and benefit outcomes.

CLINICAL ENDPOINT

Clinical endpoint is a clear, hard, clinically relevant outcome measure that is affected by the intervention under investigation and that can be objectively assessed, not depending on the investigator's judgment. A clinical endpoint is to be selected that can be reasonably and reliably assessed and can answer the primary objective. Sometimes it is difficult to achieve both aims, so in such cases clinical judgment is required. Any definitions used to characterize the primary outcome measure should be explained clearly. Sometimes two different clinically meaningful endpoints can cross-substantiate a claim for the effect of each outcome.

Medical Issues

The outcome measures chosen to evaluate the efficacy or the primary objective depends on a number of factors, including:

- Knowledge of adverse effects of closely related drugs.
- Information from nonclinical or earlier clinical trials.
- The types of subjects to be enrolled.
- Pharmacodynamic or pharmacokinetic properties of the treatment.

The endpoints should be capable of unbiased assessment. To have unbiased assessment of the endpoints, studies should be blinded. In some studies, the intervention is administered by one investigator and the measurements and evaluation of the endpoints is performed by an independent investigator not involved with the study. This is to maintain the trial integrity and to minimize bias introduced by any difference in investigators' judgments. The instrument to assess the primary variable should be reliable and accurate and adequately sensitive to detect any real change

for a subject. Clinical endpoints generally provide strong scientific evidence regarding efficacy in a targeted population. Clinical endpoints should be such that they can be assessed on all subjects. The response variable should be measured the same way for all subjects. The assessments of the response variables should be selected as standard, widely used, and generally recognized.

Statistical Issues

The sample size and power calculation for a study should be based on the primary endpoint. The endpoint could be incidence rate of an event or time to an event. Because recurrences of the primary event can occur, distribution of the number of events or frequency of episodes can be of interest in this case. Sometimes subject participation ends as soon as the primary event occurs, but sometimes the investigator wants to follow a subject for a subsequent primary variable or other secondary response variables. However, if a secondary variable occurs first, the subject must be followed, because he or she is still at risk for the primary variable. If the secondary variable is a mortality endpoint, then competing risks analyses may be appropriate.

For studies that have long-term duration, it is very important to have complete information on the subjects because if the subjects are lost to follow-up, sometimes loss of information occurs in both the treatment and the control groups. All the statistical analyses for primary or secondary variables are usually based on the intent-to-treat principle for all the randomized subjects.^[3] Sometimes post hoc analyses based on a subset of the randomized population are examined—for example, the effect of an intervention for reducing the rate of occurrence of myocardial infarction in the diabetic population, to test whether the treatment is more effective in the diabetics subset or, irrespective of the population, the treatment effect is the same. Binary data can be analyzed to obtain odds ratio or difference in proportions, and time-to-an-event data can be analyzed using proportional-hazard models, Kaplan–Meier estimates. There are additional statistical issues associated with several clinical endpoints, as shown in the next sections.

Combined Endpoints

Sometimes the primary outcome measure occurs very infrequently, so a large sample size or a long study duration is needed to have adequate power to detect a treatment difference. In this situation, combined endpoints (e.g., fatal and nonfatal myocardial infarction) are considered, to enable the detection of treatment differences with a smaller sample size or shorter study duration. This combined endpoint should have a meaningful clinical interpretation; in our earlier case it is a measure of coronary heart disease. Sometimes it is useful to combine

more than one measurement related to primary objective, e.g., rating scales in psychiatric disorders. In this case of combined endpoints, multiplicity adjustment to the type I error is not needed. Different variables of the combined endpoint can also be analyzed separately but may require multiplicity adjustment (see the next section). It is important to remember when answering a question relating to the combined endpoint that only one event per subject should be counted, and also a hierarchy of each component should be placed (for instance, the fatal myocardial infarction will be counted over the nonfatal myocardial infarction). In addition, a combined endpoint could be considered in order to achieve more power to perform subgroup analyses.

Multiple Endpoints

Multiple endpoints are different clinical events that reflect a common mechanism of action because of the intervention. Sometimes it is important to have more than one primary variable when the investigator cannot state which of several variables addresses the primary objective of the study. Use of multiple endpoints will result in an increased probability of having false-positive results. If more than one response variable is chosen, a nominal p value for each variable will be computed. If one of the multiple variables is of most importance and is most impacted by the intervention, then Bonferroni^[4] or similar adjustment methods can be used. On the other hand, if the intervention affects all the variables the same way, then adjustment is not necessary, although the effect on the type II error and the sample size should be evaluated. The O'Brien test^[5] of treatment equivalence as a global hypothesis can also be used in that case. Another way to deal with multiple correlated endpoints is to use a weighted average of the variables as a global index. The weight of each variable is the sum of the inverse variance and the covariances of that variable with the others.^[6] Thus, endpoints that are less correlated with other endpoints have more weights. When all the endpoints result in statistical significance, the study becomes more effective and assertive. For example, the clinical trial for prevention of exacerbations in multiple sclerosis using beta-interferon was based on a study where two completely different endpoints—a rate of exacerbations and an MRI-demonstrated disease activity—were used. Both endpoints were significantly decreased, which resulted in the approval.

CLINICAL VS. SURROGATE ENDPOINTS

Clinical trials with a clinical endpoint are usually longer in duration, to determine an extended exposure of the treatment. Since the clinical endpoint drives the calculation of the sample size, these trials involve a large number of subjects. On the other hand, surrogate endpoints can replace the true clinical endpoint, because it will often

result in a shorter duration and the smaller sample size of the trial. The sample size will be smaller because of the continuous nature of the data. Also, the duration of the trial will be reduced because the surrogate variables tend to change earlier in the study and the measurements can be taken at several time points.

While choosing the surrogate variables, there are certain important things to consider:

- Select the variables that have previously proven in literature to be highly correlated with the clinical endpoint.
- Choose the ones that will be accepted by the regulatory authorities and the medical community.
- Select the variables that can be reliably and accurately measured.
- Many invasive procedures should be avoided because they may result in high discontinuation rates.

According to Prentice,^[7] a valid surrogate variable should be correlated with the clinical endpoint and should capture fully the treatment's aggregate effect (accounting for all the mechanisms of action) on the clinical endpoint.

Statistical Considerations of Surrogate Endpoints

An example of a clinical endpoint in a cardiovascular trial is myocardial infarction; a surrogate variable is LDL cholesterol. Comparisons from the beginning and the end of the study or a certain interval using change or percentage change can be of interest. Comparison of slopes throughout the interval and comparison of treatments based on repeated-measures data are also analyzed.

Responder Variable

When a continuous response variable is transformed to a binary or a categorical variable it can be interpreted as a responder variable. For example, the original continuous variable percentage change in LDL cholesterol can be modified to a binary variable that takes two values: 1,

if the percentage change in LDL is less than 0; 0, if the percentage change in LDL is greater than or equal to 0. The disadvantage in creating this responder variable is that not all the information is used in the analyses, which results in loss of power.

Abstract

We describe some of the statistical approaches used in clinical endpoint studies of bioequivalence for generic drugs. We outline a conventional design and statistical analysis for such studies, including the equivalence criteria. We exemplify this approach with a more detailed discussion of studies of nasal spray products for allergic rhinitis, pointing out some of the statistical issues particular to this area, and briefly describe clinical endpoint study design and analysis recommended for equivalence determination of dry-powder inhaled products. We also discuss a case with a topical dermatological drug product to illustrate how equivalence is assessed based upon clinical endpoints, and we discuss the future statistical challenges and opportunities associated with new approaches that are being developed to evaluate equivalence for locally-acting generic topical drug products.

Keywords: Bioequivalence; Clinical endpoint studies; Locally-acting generic drugs; Two one-sided tests; Equivalence limits.

INTRODUCTION

The 1984 Drug Price Competition and Patent Term Restoration Act, known as the “Hatch-Waxman Act,” established the modern system of generic drugs in the United States. Under this system, generic drug products are considered therapeutically equivalent to the innovator reference listed drug (RLD) product if they meet the regulatory criteria of pharmaceutical equivalence and bioequivalence. Pharmaceutically equivalent drug products contain the same amount of active ingredient in the same dosage form and meet the applicable standards defined by the United States Pharmacopeia. Independently, bioequivalence (BE) is defined as “the absence of a significant difference in the rate and extent to which the active ingredient or active moiety in pharmaceutical equivalents or pharmaceutical alternatives becomes available at the site of drug action when administered at the same molar dose under similar conditions in an appropriately designed study.” The U.S. Food and Drug Administration (FDA) may accept evidence from various approaches for determining the bioavailability (BA) or BE of a drug product, including in vivo pharmacokinetic (PK) studies, certain in vitro studies that are correlated with and predictive of human in vivo BA, and well-controlled clinical studies.^[1–3]

For most oral drug products, plasma PK studies provide useful information. Levels of the drug found in the systemic circulation are directly related to bioavailability at the site of action, and parameters such as AUC (the area under the drug concentration-time PK profile in the plasma) and C_{max} (the maximum drug concentration in the plasma) are used to compare the generic and brand name (innovator) products and determine bioequivalence. For locally acting products such as topical dermatological products or those nasal sprays and inhalation products that are intended for local action, traditional plasma PK studies can be useful to evaluate systemic exposure and safety but may not necessarily be relevant for evaluating BE because the drug levels in the systemic circulation may not necessarily be representative of local bioavailability of the drug at or near the site of action. In some situations, comparative clinical endpoint studies have been used to determine BE. In this article, we describe some of the statistical approaches used in clinical endpoint studies of bioequivalence. We outline a conventional design and statistical analysis for such studies, including the equivalence criteria. We exemplify this approach with a more detailed discussion of studies of nasal spray products for allergic rhinitis, pointing out some of the statistical issues particular to this area; and briefly describe clinical endpoint study

design and analysis recommended for equivalence determination of dry-powder inhaled products. We also discuss a case with a topical dermatological drug product to illustrate how equivalence is assessed based upon clinical endpoints, and we discuss the future statistical challenges and opportunities associated with new approaches that are being developed to evaluate equivalence for locally-acting generic topical drug products.

GENERAL CONSIDERATIONS

Traditionally, in PK studies, bioequivalence has been assessed using two one-sided tests^[4] applied to the ratio of average log-transformed responses. In these cases, the generic or ‘test’ product and the innovator or ‘reference’ product (RLD) are declared bioequivalent if the 90% confidence interval (CI) of the ratio of the population geometric means is contained within the interval [0.80, 1.25]^[5]. Use of the 90% CI ensures that the total Type I error is controlled at the 0.05 level. With the equivalence limits of [0.80, 1.25], the BE ‘margin’ corresponds to a value of 1.25, and, more generally, a value of *m*, when the interval [(1/*m*), *m*] is used. These limits are philosophically related to non-inferiority margins, but bi-directional, in the sense that superiority is ruled out as well as inferiority.

Clinical endpoint studies routinely utilize this as the default approach to a statistical analysis of BE. For continuous endpoints, the FDA recommends^[6] that the following compound hypotheses are tested using the per protocol population:

$$H_0 : \mu_T / \mu_R < \theta_1 \text{ or } \mu_T / \mu_R > \theta_2 \text{ versus}$$
$$H_A : \theta_1 \leq \mu_T / \mu_R \leq \theta_2$$

where μ_T = mean of the primary endpoint for the test group (generic), and μ_R = mean of the primary endpoint of the reference (brand name) group

The null hypothesis, H_0 , is rejected with a type I error (α) of 0.05 (two one-sided tests) if the estimated 90% confidence interval for the ratio of the means between test (T) and reference (R) products (μ_T / μ_R) is contained within the interval [θ_1 , θ_2], where $\theta_1 = 0.80$ and $\theta_2 = 1.25$. Rejection of the null hypothesis supports the conclusion of equivalence of the two products.

For binary endpoints, (e.g., cure rate), the difference in proportions should be within $\pm 20\%$. The FDA

recommends^[5] that the following compound hypotheses are tested using the per protocol population:

$$H_0 : p_T - p_R < -0.20 \text{ or } p_T - p_R > 0.20 \text{ versus}$$
$$H_A : -0.20 \leq p_T - p_R \leq 0.20$$

where p_T = cure rate of test treatment and p_R = cure rate of reference treatment.

Rejection of the null hypothesis H_0 supports the conclusion of equivalence of the two products.

The 90% confidence interval for the difference in proportions between the test and reference treatments should be contained within -0.20 to 0.20 in order to conclude equivalence.

To establish sensitivity within the study for either a dichotomous or continuous primary endpoint, the test and reference product should both be significantly superior to the placebo. For this reason, whenever ethically permissible, a placebo third arm is included in a clinical endpoint study.

We note that the primary clinical endpoint may be, but is not necessarily the same as, that used in the studies submitted in the NDA for the RLD. For example, the registration study may evaluate the success of the trial at thirty days, while the Abbreviated New Drug Application (ANDA) study may recommend the same measure evaluated at 15 days.

Some examples of clinical endpoint studies for locally-acting products are given below.

Anti-fungal cream

In the case of topical dermatological dosage forms (such as creams, ointments and gels) the drug is intended to act locally near the site of application on the skin, and typically cannot be monitored in the systemic circulation. Clinical endpoint studies have been used as a standard approach to evaluate BE.

As an example of such a situation, the FDA draft guidance^[7] recommends a clinical endpoint study for demonstrating equivalence to the RLD for ciclopirox cream, an antifungal agent commonly used in the treatment of several dermal infections. Signs and symptoms are to be graded on a four-point scale (Table 1).

A case study of a clinical endpoint trial in an ANDA for this product can be found in Peters’ chapter, “Clinical Endpoint Bioequivalence Study,” in Yu and Li, editors.^[5] This was a multicenter, parallel group study for the treatment of tinea pedis, with 462 patients randomized in a

Table 1 Skin grading scale

Signs (physician assessment)	Symptoms (patient assessment)	Scoring Scale
Erythema	Pruritus	0 = none (complete absence of any signs or symptoms)
Scaling	Burning/Stinging	1 = mild (slight)
Fissuring/Cracking		2 = moderate (definitely present)
Masceration		3 = severe (Marked, intense)

Table 2 Per protocol results - cure rates

	Generic	RLD	Difference in rates (90% CI)	Is confidence interval within + 20%?	Pass equivalence?
Therapeutic cure	50%	46%	4% (-5%, 14%)	Yes	Yes
Clinical cure	64%	63%	1% (-9%, 10%)	Yes	N/A
Mycological cure	78%	73%	5% (-2%, 15%)	Yes	N/A

2:2:1 ratio to receive one of three treatments (ciclopirox, the RLD Loprox® or the placebo). Patients returned for clinical evaluations at Days 15, 29, and 43.

The primary endpoint of the clinical endpoint BE study was the proportion of subjects with therapeutic cure at week 6, defined as both clinical cure and mycological cure. Clinical cure was defined as a total clinical score (sum of severity scores on signs and symptoms) of 2 or less, with a score of no more than 1 for any of the clinical parameters at Visit 3 (Day 43). Mycological cure was defined as a negative culture at visit 3.

These proportions (cure rates) were calculated and compared for week 6 (Table 2).

Equivalence was evaluated by comparing rates of therapeutic cure for the per-protocol population. The data and results from this clinical endpoint study were deemed to support equivalence.

Nasal sprays

The evaluation of BE for nasal spray drug products that are intended to act locally demonstrates the need for a clinical endpoint study, and also illustrates the issues that arise in the design and analysis of such studies. These drug products are used, for example, to treat seasonal allergic rhinitis (SAR). Use of plasma PK studies alone is currently considered insufficient to establish equivalence because these products do not rely on systemic circulation for delivery to the site of action in the nasal passages.^[3] Beyond the potentially limited relevance of plasma PK, demonstrating BE in this situation through clinical endpoint studies poses particular statistical problems in the design and analysis. With the increasing number of applications for generic nasal spray drug products in the U.S., these problems are of increasing interest. This section describes current approaches to the design and analysis of clinical studies for determining equivalence for nasal spray products.

The FDA recommends conducting a clinical endpoint BE study for approval of generic nasal sprays indicated to treat SAR. According to the 2003 FDA Draft Guidance on Bioavailability and Bioequivalence Studies for Nasal Aerosols and Nasal Sprays for Local Action,^[8] the study should consist of 2 periods: an initial 7-day single-blind, placebo run-in period (Study Days -7 to -1) to establish a baseline and to identify placebo responders, followed by a 14-day treatment period (Study Days 1 to 14). Assessments are made twice daily, AM (before Noon) and PM (after Noon). A typical study design for a nasal spray study is illustrated in Fig. 1.

In general, patients who have a reflective total nasal symptom score (rTNSS; defined below) of at least 6 out of the total of 12 at screening (24 hours prior to run-in) with a history of SAR and a positive test for relevant specific allergens are allowed to enter into a single-blind placebo run-in period, during which all subjects are to receive the placebo vehicle administered daily for 7 days.

It is expected that a placebo will provide some clinical benefit, and the draft guidance recommendation allows the first four days of the baseline period for the participants to achieve their placebo symptom level. Placebo responders should be identified during the placebo run-in period. Under this assumption, the draft guidance recommendation is to use only assessments from days -3, -2, and -1 of the baseline period (plus the AM assessment from day 1) to determine baseline level.

The draft guidance also recommends that placebo responders should be excluded from the study to increase the ability to show a significant difference between active and placebo treatments, and to increase sensitivity to detect potential differences between Test and Reference products. Placebo responders should be defined a priori. Subjects are considered potential placebo responders if the average baseline reflective total nasal symptom (rTNSS) is less than six out of the maximum of 12.

**Fig. 1** Nasal spray study design

The treatment period itself should be a randomized, double-blind, placebo-controlled, parallel group trial. All subjects who qualify after the placebo run-in period are to be randomized to receive the generic nasal spray, the RLD or placebo vehicle during the treatment period. During the treatment period, the study drug is to be administered daily for 14 days. The draft guidance recommendation is to use the PM assessment on day 1 and the AM and PM assessments from days 2 to 14 of treatment period.

The total nasal symptom score (TNSS) is defined as the sum of subject-rated severity scores for runny nose, nasal congestion, nasal itching, and sneezing at each assessment time. The evaluation of TNSS is made twice daily (AM and PM) approximately 12 hours apart throughout the 7 day run-in period and the 14-day randomized treatment period. The severity score for each symptom is based on a 4-point scale:

- 0 = none
- 1 = mild
- 2 = moderate
- 3 = severe

There are two scores assessed at each time: the reflective TNSS (rTNSS), defined as the evaluation of symptoms during the period of time since the last assessment, and the instantaneous TNSS (iTNSS), which is evaluation of symptoms at that moment.

Outcome variables are based on averaged TNSS over the baseline period and over the treated period. The response of interest is the change from baseline, defined as (baseline mean TNSS) – (mean TNSS under treatment)

The primary endpoint is the change from baseline mean rTNSS to the treatment mean rTNSS.

A general linear model including the treatment and the site as factors and including the baseline as a covariate is used to analyze the efficacy (superiority of active

treatments over placebo) and equivalence. The model is based on empirical experience: in historical data from nasal spray clinical endpoint studies, we have observed a highly statistically significant linear relationship between the response variable (change from baseline in rTNSS) and baseline value. The inclusion of the baseline covariate in the statistical model results in an important reduction in the residual variance, at least for the efficacy analyses.

For the equivalence analyses, the same ANCOVA model is used to calculate adjusted least squares means for the test and reference groups. Ninety percent (90%) confidence intervals for the ratio of these least squares means are calculated using Fieller's method.^[9]

There is another twist to evaluating statistical equivalence for nasal spray products. In the assumed ANCOVA statistical model with the baseline as a covariate, the mean response (mean change-from-baseline) for a given product is a linear function of the baseline. Since, in our experience, the estimated slope is positive (which we would expect because higher baseline values allow for more of a chance for the score to decrease) we assume that the slope relating the response to the baseline is positive. That is, the mean response is higher for higher values of the baseline.

Under the assumed linear model, the difference between the mean response to the test product and the mean response to the reference product is constant and independent of the baseline. But the ratio of the test product mean to the reference product mean depends on the baseline. Therefore, for higher values of the baseline, the ratio of the test and reference means is necessarily closer to one. The possibility exists that the products could be inequivalent (have a ratio of means less than 0.80 or greater than 1.25) for a given value of the baseline, but equivalent for a higher value of the baseline.

The graph below illustrates typical behavior of CI and point estimates as a function of baseline values for the

Fig. 2 90% confidence Intervals and point estimates for the ratio of the Test mean over the Reference mean (primary endpoint)

ratio of means (Fig. 2). Note that the curve connecting the point estimates approaches 1 as the baseline increases. The dashed vertical line shows the minimum value of the baseline for which the products pass the usual equivalence test for the mean change from the baseline.

In practice, we use the model to calculate the 90% CI at the average of the baseline values for the study population and check that the CI falls within the equivalence limits, in effect, checking that the study average baseline is larger than the dashed vertical line seen on a study-specific graph similar to Fig. 2.

Dry powder inhalers

The FDA issued a draft Guidance for Industry in September 2013 outlining recommendations for studies to be included in ANDA submissions to establish bioequivalence of the test and reference dry powder inhalers (DPIs) containing fluticasone propionate 100 mcg and salmeterol xinafoate 50 mcg (100/50 strength).^[10] This product is indicated to treat asthma and chronic obstructive pulmonary disease (COPD).

The draft guidance recommends conducting a clinical endpoint BE study along with in vitro studies and an in vivo PK study for approval of a generic DPI. The clinical endpoint study should consist of 2 periods, a single-blind, placebo run-in period of at least two weeks duration to wash out any pre-study corticosteroids or long acting bronchodilators and to establish baseline values of forced expiratory volume in 1 second (FEV₁); followed by a 4-week treatment period with the placebo, test or reference product. In general, subjects ≥ 12 years of age diagnosed with asthma as defined by the National Asthma Education and Prevention Program (NAEPP)^[11] at least 12 weeks prior to screening are eligible for the study.

During the study period, subjects take one inhalation of study medication twice a day (morning and evening). Assessments are made on the first day of treatment (Day 1) to determine FEV₁ at 0, 0.5, 1, 2, 3, 4, 6, 8, 10 and 12 hours post-dose as well as on the last day of a 4-week treatment to measure FEV₁ in the morning prior to the dosing of inhaled medications.

BE study endpoints are based on (i) Area under the serial FEV₁-time curve calculated from time zero to 12 hours (AUC_{0-12h}) on the first day of the treatment, and (ii) FEV₁ measured in the morning prior to the dosing of inhaled medications on the last day of a 4-week treatment.

The above two primary endpoints should be baseline adjusted through using the change from baseline. A FEV₁ baseline is defined as the average of pre-dose FEV₁ values of at least two time points measured in the morning of the first day of a 4 week treatment period. Sampling is recommended to correspond to the same time of day as used on the last day of a 4-week treatment.

The current statistical analysis approach is similar to that for a nasal spray study. Analysis of covariance (ANCOVA)

is used to analyze the superiority of active treatments over placebo and determine equivalence between active products; a general linear model is fit, including the treatment and the site as factors and the baseline as a covariate.

To ensure adequate study sensitivity, the T and R products should both be statistically superior to placebo ($p < 0.05$) in regards to the BE study primary endpoints.

Equivalence is based on the T/R ratio for the primary endpoints. The 90% CIs for the T/R ratios for the primary endpoints should fall within the limits of 80%–125%. The same ANCOVA model as the one mentioned above is used to calculate adjusted least squares means for the test and reference groups for the equivalence analyses. Ninety percent (90%) confidence intervals for the ratio of these least squares means are calculated by Fieller's method.

In addition, all adverse events (AEs) should be reported, whether or not they are considered to be related to the treatment. The report of AEs should include date of onset, description of the AE, severity, relation to study medication, action taken, outcome and date of resolution. This information is needed to determine if the incidence and severity of adverse reactions is different between the T and R products.

DISCUSSION

Clinical endpoint studies and nasal spray products

There is continued discussion in the literature about the appropriateness of the ANCOVA model in various situations, especially when we use baseline and post treatment measures in the statistical model for treatment comparisons in clinical trials. In practice, it is known that by incorporating the baseline information in the analysis, we can effectively reduce the variance of the estimated treatment effect. Use of the baseline as a covariate and analysis of difference of pre- and post-treatment measures are two ways to accomplish this. Senn^[25] has shown that the use of analysis of covariance as a means of adjusting for baseline measurements is appropriate in randomized clinical trials. He also makes the point that it is not a necessary condition for groups to be equal at baseline for ANCOVA to provide unbiased estimates of treatment effects. Even in analyses in which the change from the baseline is the response and the baseline is used as a covariate, the treatment efficacy comparisons are identical to those derived using the post-treatment measures as the response in ANCOVA.^[25,26]

This identity will not hold in equivalence tests where we are using the ratio of means as our test statistic. The change from baseline is necessarily smaller in magnitude than the post-treatment value and so which of these two quantities is used as the response value will affect the outcome of the equivalence test, and not consistently. In practice, the

change from the baseline has been established as the quantity of interest in both efficacy and equivalence testing; more so than for new drugs, precedent is followed in generic drug trials unless there is a persuasive reason to ignore it.

In determining the equivalence of nasal spray products for marketing approval, the estimate of the CI of the ratio calculated by Fieller's method provides the means for bioequivalence testing. In general, ratios of two random variables do not have good distributional properties and it is not straightforward to construct the corresponding CI. In practice, Fieller's method is often used for jointly normally distributed data to construct closed-form confidence regions of ratios (μ_T/μ_R). In our experience, the distribution of response values (change from baseline) tends to be moderately skewed. Luxburg and Franz have shown that Fieller's method behaves reasonably well even for asymmetric distributions.^[27]

There are other approaches that have been introduced in the literature in an attempt to relax the assumption of normality when estimating the confidence sets for ratios. But these methods should be used with caution and may not be appropriate for bioequivalence assessment. Luxburg and Franz introduced a geometric approach to construct confidence sets for ratios for more general classes of distributions.^[27] This approach will lead to conservative confidence sets for the ratio, with coverage greater than the nominal level and a higher chance of failure for the generic. An alternative is to consider numerical simulation methods such as the bootstrap. These methods, however, may be problematic in regulatory settings since, in addition to theoretical problems, the results may not be reproducible due to the randomness inherent in the calculations. In addition, it would be challenging to incorporate aspects of the nasal spray data, for example the positive linear relationship between the response and the baseline, in a bootstrap calculation or other nonparametric approach.

Topical dermatological products and IVPT

Clinical endpoint studies have been used as a standard approach to evaluate BE, and can play an important role in assessing the BE of locally-acting drug products, but these studies are not necessarily considered to be the most accurate, sensitive, and reproducible for evaluating BE.^[2] This is, in part, because the permeability of diseased skin to the drug can be altered depending upon the severity of the disease state, which can influence the BA of the drug in a heterogeneous way that introduces variability into the study; placebo effects can be very high for a variety of reasons; clinical endpoint evaluations may be based upon subjective assessments; patient compliance to the therapeutic regimen can be an issue, particularly because of the ability of the patient to continually observe the condition of their skin (those who suspect themselves to be in a placebo treatment group may revert to using other treatments to reduce social embarrassments associated with their

skin disease); and the natural cycles of exacerbation and resolution of the disease can lead to improvements in the endpoint over time, that may be unrelated to the effect of the treatment, and which can reduce the sensitivity of the clinical endpoint evaluations which are often performed several weeks following the initiation of treatment. Due to the inherent variability in results, the relatively high placebo effect, and the relative insensitivity of the assessment endpoint(s), these studies may require a very large number of subjects in order to be adequately powered.^[12–15]

Research is underway to explore the feasibility of potentially more efficient, sensitive and discriminating approaches to evaluate BE based upon the collective weight of evidence from extensive comparative characterizations of the RLD and generic product, supplemented by biologically relevant evidence of comparative BA from an in vitro permeation test (IVPT), which evaluates the rate and extent of drug delivery into and through excised human skin. However, in order to assess the equivalence of comparative BA based upon IVPT results, it is necessary to develop statistical methodologies that are appropriate to the inherently replicate design of these studies^[3] and to the highly nature of the resulting data.^[24]

CONCLUSION

During the decades since the Hatch-Waxman generic drug legislation was enacted, high quality generic versions of systemically acting oral drug products have become almost ubiquitous, and this has had a tremendously positive social impact in the United States. Current research is focused on developing suitable approaches to facilitate the evaluation of BE for drug products that act locally. While the scientific merits of such approaches are being investigated, it is essential to ensure that appropriate statistical methodologies are also developed to support the use of those alternative study designs to evaluate BE. It is hoped that clinical trial designs and analyses such as those described in this article as well as applications of novel statistical methodologies can aid in the efforts to make high quality generic medicines increasingly available to the American public.

Abstract

Regulatory inspection of clinical trial is necessary in order to (1) assess compliance with statutory requirements and regulatory requirement governing the conduct of clinical trials and (2) verify the accuracy and reliability of clinical trial data submitted to regulatory agencies such as the United States Food and Drug Administration (FDA) in support of research or marketing applications. This article provides an overview of clinical inspection process and issues that are commonly encountered during the conduct of clinical trials. In addition, a couple of sampling plans for clinical inspection of relatively large trials are proposed. The proposed statistical process for clinical inspection that will achieve a desired degree of inspection accuracy and reliability is useful when the resources of inspectors are limited. The proposed two-stage sampling plan can be applied to clinical inspection for multicenter and/or multinational multicenter clinical trials.

Keywords: Acceptance quality level; FDA 483 observations; Inspection accuracy and reliability; Two-stage sampling plan.

INTRODUCTION

ICH E6 guidance for *Good Clinical Practice* (GCP) defines (regulatory) inspection as the act by a regulatory authority of conducting an official review of documents, facilities, records, and any other resources that are deemed by the authority to be related to the clinical trial and that may be located at the site of the trial, at the sponsor's and/or contract research organization's (CROs) facilities, or at other establishments deemed appropriate by the regulatory authority.^[1] To assist the sponsors of clinical trials, the United States Food and Drug Administration (FDA) developed a bioresearch monitoring (BIMO) program to ensure the protection of the rights, safety, and welfare of human research subjects involved in FDA-regulated clinical trials. The purpose is not only to assess compliance with statutory requirements and FDA regulations governing the conduct of clinical trials but also to verify the accuracy and reliability of clinical trial data submitted to the FDA in support of research or marketing applications. For this purpose, in 2010, the FDA published a guidance "Information Sheet Guidance for IRBs, Clinical Investigators, and Sponsors—FDA Inspections of Clinical Investigators."^[2] The FDA conducts clinical investigator inspections of clinical investigators under the FDA's BIMO program is to determine if the clinical investigators are conducting

clinical studies in compliance with applicable statutory and regulatory requirements.

Regulatory inspections are important to evaluate the integrity of the data submitted to health authorities, the presence of infrastructure to conduct clinical research, measures implemented to protect patient's interest and safety, adequacy of site/sponsor quality systems, and verification of compliance with the principles of ICH-GCP as well as local regulations.^[3] In practice, although inspections can occur at any time, they generally occur after submission of data for marketing approval of an investigational drug. The inspectors generally conduct a thorough review of site data including all aspects of ICH-GCP, site infrastructure, and quality control procedures and system before inspections. Findings are discussed during the closeout meeting and a detailed inspection report issued afterward. The sponsors usually respond within 15–30 days with effective corrective and preventive action (CAPA) plan. In clinical trials, protocol noncompliance, inadequate/inaccurate records, inadequate drug accountability, informed consent issues, and adverse event reporting were some of the most common deficiencies observed during recent FDA inspections.^[3]

Clinical inspection of a relatively large clinical trial or multicenter or multinational multicenter clinical trial could be labor intensive and time consuming. It may not be feasible if there are limited resources available. Alternatively, one

may consider adopting a statistical process by inspecting a randomly selected proportion of subjects such as informed consents and case report forms (CRFs) for achieving a pre-specified inspection accuracy and reliability. A valid statistical process consists of sampling plan, acceptance criteria, and testing procedure. Under the statistical process for clinical inspection, the inspector will prespecify an acceptance quality level (AQL) or a desired inspection accuracy and/or reliability and then conduct inspection according to the sampling plan for achieving the desired inspection accuracy and reliability.

In this article, process and some general principles for clinical trial inspection are briefly outlined. FDA Form 483 observations and actions that need to be taken are discussed. Examples of top 483 observations issued by the FDA between 2006 and 2014 are also included. Statistical process including sampling plan, acceptance criteria, and testing procedure for clinical trial inspection is described and discussed. Some concluding remarks are given in the last section of this article.

INSPECTION PROCESS

Scope of Inspection

For clinical inspection, all site personnel who have a significant role in the conduct of clinical trial should be present during the inspection. These personnel usually include, but are not limited to, principal investigator (PI), sub-investigators (SIs) or co-PI, study coordinator (SC), laboratory personnel, and pharmacist. In many cases, trial sponsor representatives may also be present at the site to facilitate the process. It, however, should be noted that the sponsor representatives should not make any attempts to interfere site inspection.

Clinical inspection generally involves a facility tour for evaluation of site infrastructure, site's standard operation procedures (SOPs), and process of clinical trial operation including data collection/entry, data verification/validation, and data management for quality assurance to make sure the conduct of clinical trials is in compliance with GCP. Clinical inspection may include inspection of laboratories if trial-related laboratory tests are done locally. Laboratory inspection includes review of laboratory equipment, process, calibration, quality assurance/control method, and related documents for Good Laboratory Practice such as SOPs for training and handling of study specific laboratory testing procedures; archival storage of test samples; and stock checks, labeling, and accountability logs.

Note that clinical inspection may also include insurance coverage for subjects and a disaster plan in case of an emergency such as fire or flood, among others.

Before Inspection

Before inspection, it is suggested that a designated person (usually the research coordinator for the study) be identified

to serve as institutional monitor who will escort and oversee the inspection. The identified individual should complete the FDA audit checklist and identify records and/or documents that the FDA inspectors are likely to audit. The records and/or documents that the FDA are likely to inspect include, but are not limited to, (1) all informed consents forms and subject enrollment and screening log, and (2) all or selected CRFs or case record books (CRBs) and all supportive source documentation. All or selected CRFs (or CRBs) depends upon sampling plan adopted for the inspection, which will be discussed at later section of this article.

The inspection starts with an opening meeting. The inspector will present a *Notice of Inspection* (482) to the PI. This notice authorizes the inspection, and its presentation officially begins the inspection. The inspector will explain the intended purpose and scope of the inspection, then ask the PI to summarize the study. The PI/site representative will then make a general presentation about the site and study, and address initial questions from inspectors. It is an appropriate time to discuss the inspection schedule, availability of site personnel, logistic arrangements, etc., to ensure smooth conduct of inspection with minimum interference in routine site schedule. If there were important deviations from GCP, it might be wise to be up front with the inspectors and explain why they happened and how measures were taken to prevent them from happening again.

Note that the FDA investigator must not be permitted free access to areas where files are kept, and the escort serves as an institutional monitor as well as guide and general study contact person.

The Inspection

The inspection focus is usually on the investigator role in the study, delegation of duties (with documentation), qualification of site staff, and ethical issues (e.g., consent process and ethic committee review). The inspection also involves team member interviews—PI, SI, SC, lab personnel, and others. Sponsor/monitor may also be interviewed to evaluate their supervision, protocol knowledge, and adequacy to identify and resolve issues.

The inspector usually starts with the general study materials (or master files) including the regulatory documents/binders, then all signed informed consent forms, followed by a sampling of specific patient records. The data review generally includes subject history, informed consent, subject eligibility, investigational drug administration, compliance, safety reporting, compliance to study procedures, and other study-specific issues. There is a frequent interaction between inspectors and site personnel to clarify points and issues, and to provide supporting documents.

Only documents specifically requested by the inspector shall be provided for review. The escort may need to obtain patient records from the hospital or clinic records to supplement or corroborate the research records. The

inspector must never have access to any site records not specifically provided by the host. Standard procedure is for the inspector to request files for review.

Note that the inspector is not entitled to review or copy financial, personnel (except for training/qualification records), and internal audits (section 704(a) FDC Act).

Exit Interview

The FDA will usually hold an exit interview (or closeout meeting) at the conclusion of the inspection. This also provides opportunity for site personnel to clarify any points concerning the findings or to provide better context. The designated institutional monitor, PI, and other individuals as appropriate should be notified of the time and place and expected to attend. Note that the sponsor may attend the closeout meeting only if the PI agrees. At the exit interview, the PI will usually seek to correct any errors in the findings. Both the FDA and the PI will make sure everything is clear and understood. The institutional monitor should take noted on observations, comments, and commitments discussed at the closeout meeting.

During this exchange, if serious deficiencies have been found during the inspection, an FDA Form 483 (Inspectional Observations) will follow from the regional office, listing the deficiencies. If no deficiencies are found, or the inspector has comments that she or he believes are not serious enough to warrant a 483, no form will be issued. At the closeout meeting, FDA Form 483s are discussed with a company’s management at the conclusion of the inspection. Each observation is read and discussed so that there is a full understanding of what the observations are and what they mean.

FDA 483 OBSERVATIONS AND ACTIONS

FDA 483 Observations

The FDA is authorized to perform inspections under the Federal Food, Drug, and Cosmetic Act (FD&C Act), Sec. 704

(21 USC §374). FDA Form 483 (Inspectional Observations) is a form used by the FDA to document and communicate concerns discovered during these inspections (see also [4]). The FDA Form 483 notifies the company’s management of objectionable conditions. At the conclusion of an inspection, the FDA Form 483 is presented and discussed with the company’s senior management. Companies are encouraged to respond to the FDA Form 483 in writing with their corrective action plan and then implement that plan expeditiously. Note that the FDA inspector will file an establishment inspection report within approximately 30 days.

The FDA Form 483 is a report that does not include all observations of questionable or unknown significance at the time of the inspection. There may be other objectionable conditions that exist at the sponsor that are not cited on the FDA Form 483. FDA investigators are instructed to note only what they saw during the course of the inspection. Companies are responsible for taking corrective action to address the cited objectionable conditions and any related non-cited objectionable conditions that might exist.

It should also be noted that the FDA Form 483 does not constitute a final agency determination of whether any condition is in violation of the FD&C Act or any of its relevant regulations. The FDA Form 483 is considered, along with a written report called an Establishment Inspection Report, all evidence or documentation collected on site and any responses made by the company. The agency considers all of this information and then determines what further action, if any, is appropriate to protect public health.

As an example, Tables 1 and 2 give a list of top 10 FDA Form 483 observations for pharmaceuticals and devices, respectively. The top three 483 observations for pharmaceuticals are (1) procedures not in writing, fully followed (169); (2) investigations of discrepancies and failures (119); and (3) absence of written procedures (116). The top three 483 observations for devices are (1) lack of or inadequate procedures (372), (2) lack of or inadequate complaint procedure (259), and (3) lack of written MDR procedures (140). On the other hand, Fig. 1 plots total 483s issued by

Source: <http://www.raps.org/Regulatory-Focus/News/2014/12/08/20928/The-Top-15-Pharmaceutical-Deficiencies-Cited-by-FDA-in-2014/>.^[5]

the FDA between 2006 and 2014. As it can be seen, the number of 473s issued (645) marked the second consecutive year thw FDA has issued fewer pharmaceutical 483s than the year prior, and the 2014 total (645) is 19% less than its 2012 high water mark (787 inspections).

Actions

The PI or designated personnel is responsible for drafting a written response to the FDA. The written response should be able to address each particular observation or finding point by point and delineate corrective actions, including justification of why the proposed response will remediate the issue and a realistic timeline for correction. The PI should also determine if a finding was an oversight/one-time occurrence or systemic, where a change of procedure is indicated. If the PI disagrees with an observation, respond factually, providing clear and verifiable evidence. It should be noted that the response should be sent within 2 weeks and a signed copy should be kept in the master file of the clinical trial.

In practice, the following steps for formulating a response to dealing with each FDA 483 observation are often considered (see Table 3).

Note that steps 1 through 7 are directly related to formulating a response to the observation. It is critical to

understand that steps 6 and 7 directly relate to the response letter in that these actions determine the time frame in which actions can be accomplished.

STATISTICAL PROCEDURE

For clinical trial inspection, the inspector will conduct inspection on site. The scope of inspection includes facility/site infrastructure, SOPs, and process of clinical trial operation including informed consents and clinical data capture. The primary focus of clinical inspection is on quality and validity of clinical data captured by CRFs or CRBs. For a large clinical trial, a complete clinical inspection could be very time consuming, especially when there are limited resources available. In this case, some sampling plans with prespecified acceptance criteria for clinical trial inspection could be useful.

Hypergeometric Distribution

Let N be the population size (i.e., number of CRBs or size of the clinical trial) and K be the CRBs with deficiencies (or failures). Then $P = K/N$ is the true proportion of failures (deficiencies). Also let $X = (X_1, X_2, \dots, X_n)$ be a

Table 3 An approach for formulating a response to each observation

Step	Description	Comment
1	Evaluate the current state of compliance in light of the audit observation	If possible, indicate what is compliant
2	Identify the root cause of the issue as appropriate	Understand how the firm will resolve the issue systemically
3	Review prior commitments	Repeated observations also greatly increase the likelihood of further regulatory actions
4	Identify the root cause	This is a fundamental principle in the FDA's view of systemic audits
5	Relate each observation to the appropriate quality system	Understand the area of impact of the issue in relation to the functions impacted by that system
6	Develop a corrective action plan	Around the entire scope of the issue(s) noted
7	Secure the required resources	Need to complete the job in the time frame indicated
8	Verify that responsibilities are assigned to key people	Make them accountable

random sample drawn from the population of size N without replacement. Thus, $S = \sum_{i=1}^n X_i$ follows a hypergeometric distribution with the probability density as follows:

$$P\{S = r\} = \frac{\binom{NP}{r} \binom{N-NP}{n-r}}{\binom{N}{n}} \quad (1)$$

The mean of S is nK/N and the variance is

$$n \frac{K}{N} \frac{(N-K)}{N} \left(\frac{N-n}{n-1} \right) = nP(1-P) \left(\frac{N-n}{n-1} \right)$$

Note that if N is extremely large, it is possible that even without replacement, the results may approximate the binomial distribution (sampling with replacement). Alternatively, we may consider normal approximation when N is sufficiently large. Denote $p = S/n$. Then, the corresponding z is given by

$$z = \frac{p - P}{s}$$

where

$$s = \sqrt{\frac{P(1-P) \frac{N-n}{N-1}}{n}}$$

Denote by δ the accuracy of the proportion P . Thus, for achieving this accuracy with certain probability (say $1 - \alpha$), the sample size required satisfies the following inequality:

$$P\{|p - P| \leq \delta\} \geq 1 - \alpha$$

As a result, we have

$$n \geq \frac{N^2 z_{\alpha/2}^2 P(1-P)}{\delta^2 (N-1) + z_{\alpha/2}^2 P(1-P)} \quad (2)$$

where $z_{\alpha/2}^2$ is the $\alpha/2$ quantile of standard normal distribution.

Single-Stage Sampling Plan

Let P_0 be the acceptable quality level (AQL) that is defined as the minimum level of quality or the maximum fraction of error rates that is acceptable to the inspector. In this case, if $P < P_0$, we claim that the study site meets AQL. Thus, for a clinical trial inspection, the following one-sided hypothesis is commonly considered for testing whether the study site meets a prespecified AQL P_0 :

$$H_0 : P = P_0 \quad \text{vs.} \quad H_a : P = P_1 \quad (3)$$

where $P_1 = P_0 - \delta$, $0 < \delta < P_0$, which is referred to as a desirable AQL. In practice, we would reject the null hypothesis and conclude the alternative hypothesis that the study site has met desirable AQL with an appropriate choice of δ . To test hypotheses in Eq. 3, various tests such as exact test or normal-based method can be considered.

Exact test—Given sample size n , for any integer C that $0 \leq C \leq NP$, we have

$$P\{S \leq C | P\} = \sum_{s=0}^C \frac{\binom{NP}{s} \binom{N-NP}{n-s}}{\binom{N}{n}}.$$

Given α , the level of significance, we choose the largest C that satisfies

$$P\{S \leq C | P = P_0\} \leq \alpha$$

If we denote this C by $C_{n, \alpha}$, power is given by

$$P\{S \leq C_{n, \alpha} | P = P_1 = P_0 - \delta\}$$

Thus, for a given β , we can choose the smallest n satisfying

$$P\{S \leq C_{n,\alpha} \mid P = P_1 = P_0 - \delta\} \geq 1 - \beta$$

Although this test is based on the exact hypergeometric distribution, there exists no closed form for the smallest sample size n that satisfies the error rate constraints. In practice, the interval searching for $C_{n,\alpha}$ can be obtained from $\max\{0, n - (N - NP_0)\}$ to $\min\{NP_0, n\}$.

Normality-based test—Under the null hypothesis of Eq. 3, the following test is useful:

$$T_p = \sqrt{\frac{n}{P(1-P)^{\frac{N-n}{N-1}}}} (p - P) \quad (4)$$

where $p = S/n$. For large sample size, T_p is approximately normal distributed. Thus, we have

$$P\{T_{p_0} \leq -z_\alpha \mid P = P_0\} \approx \alpha$$

where z_α is the α th quantile of standard normal distribution. Thus, we take the set of $\{T_{p_0} \leq -z_\alpha\}$ as the rejection set. To achieve the power of $1 - \beta$, we choose the smallest n satisfying

$$P\{T_{p_0} \leq -z_\alpha \mid P = P_1\} \geq 1 - \beta$$

Under the approximate normality, we have

$$\begin{aligned} & P\{T_{p_0} \leq -z_\alpha \mid P = P_1\} \\ &= P\left\{\sqrt{\frac{n}{P_1(1-P_1)^{\frac{N-n}{N-1}}}} (p - P_1) \leq -z_\alpha \sqrt{\frac{P_0(1-P_0)}{P_1(1-P_1)}} \right. \\ &\quad \left. + \delta \sqrt{\frac{n}{P_1(1-P_1)^{\frac{N-n}{N-1}}}} \mid P = P_1 = P_0 - \delta\right\} \\ &\approx \Phi\left(-z_\alpha \sqrt{\frac{P_0(1-P_0)}{P_1(1-P_1)}} + \delta \sqrt{\frac{n}{P_1(1-P_1)^{\frac{N-n}{N-1}}}}\right) \end{aligned}$$

Thus, we have

$$n = \frac{N}{\frac{(N-1)\delta^2}{P_1(1-P_1)\left(z_\beta + z_\alpha \sqrt{\frac{P_0(1-P_0)}{P_1(1-P_1)}}\right)^2 + 1}} \quad (5)$$

where z_β is the β th quantile of standard normal distribution.

As a result, the single-stage sampling plan for clinical inspection can be summarized as the following steps:

Step 1: Set up the AQL P_0 (or $P_0 - \delta$).

Step 2: Determine the sample size required n (or the number of acceptable deficiencies c , where $c = nP_0$ for achieving a desired statistical inference).

Step 3: Conduct clinical inspection of the selected n subjects (or CRBs).

Step 4: Determine whether the study site has passed or failed the clinical inspection based on whether they have met the prespecified AQL.

Two-Stage Sampling Plan

The idea of single-stage sampling plan can be extended to a two-stage sampling plan. In other words, we randomly select n_1 subjects at the first stage. If the n_1 subjects meet a prespecified AQL at the first stage, we claim that the site has passed clinical inspection; otherwise, proceed to the second stage of inspection. At the second stage, additional n_2 subjects will be randomly selected from the population. If the $n_1 + n_2$ subjects meet a prespecified AQL at the second stage, we conclude that the site has passed clinical inspection; otherwise, the site has failed clinical inspection.

Let $(X_1, X_2, \dots, X_{n_1})$ be a random sample at stage 1. Denote $S_1 = \sum_{i=1}^{n_1} X_i$. We then reject the null hypothesis of Eq. 3 and stop clinical inspection if $S_1 \leq C_1$. On the other hand, we will accept the null hypothesis and stop clinical inspection if $S_1 > C_2$, where C_1 and C_2 are some constant integers, where $C_1 < C_2$. If $C_1 < S_1 \leq C_2$, then proceed to stage 2 and randomly draw additional n_2 subjects, i.e., $(X_{n_1+1}, X_{n_1+2}, \dots, X_{n_1+n_2})$. Let $S_2 = \sum_{i=n_1+1}^{n_1+n_2} X_i$. We then reject the null hypothesis when $S_1 + S_2 \leq C_2$.

For this two-stage sampling plan, the overall sample size is n_1 if the null hypothesis is rejected at stage 1; otherwise, the overall sample size is $n_1 + n_2$. As a result, the expected sample size of this two-stage sampling plan is given by

$$E(n \mid P) = n_1 + n_2(1 - PET_p) \quad (6)$$

where PET_p is the probability of early termination of the two-stage sampling plan when the true value of the proportion is P . Now, given n_1, n_2, C_1, C_2 , and P , we have

$$\begin{aligned} PET_p &= H_1(\min\{n_1, NP\} \mid P, n_1) \\ &\quad - H_1(\min\{C_2, n_1, NP\} \mid P, n_1) + H_1(C_1 \mid P, n_1) \end{aligned} \quad (7)$$

and

$$\begin{aligned} P(\text{reject} \mid P, n_1, n_2, C_1, C_2) &= H_1(C_1 \mid P, n_1) \\ &\quad + \sum_{s_1=C_1+1}^{\min\{n_1, C_2, NP\}} h(s_1 \mid P, n_1) H_2(C_2 \mid P, n_1, n_2, s_1) \end{aligned} \quad (8)$$

where

$$\begin{aligned}
 h(s_1 | P, n_1) &= \frac{\binom{NP}{s_1} \binom{N-NP}{n_1-s_1}}{\binom{N}{n_1}} \\
 H_1(C_1 | P, n_1) &= \sum_{s_1=\max\{0, n_1-(N-NP)\}}^{\min\{C_1, n_1, P\}} h(s_1 | P, n_1) \\
 H_2(C_2 | P, n_1, n_2, s_1) &= \sum_{i=\max\{0, (n_1+n_2)-(N-NP)-s_1\}}^{\min\{C_2, NP, (n_1+n_2)\}-s_1} \frac{\binom{NP-s_1}{i} \binom{N-NP-(n_1-s_1)}{n_2-i}}{\binom{N-n_1}{n_2}} \quad (9)
 \end{aligned}$$

Given α and β , since there exist no closed forms for n_1 , n_2 , C_1 , and C_2 that satisfy the following constraints:

$$\begin{aligned}
 P\{\text{reject} | P_0, n_1, n_2, C_1, C_2\} &\leq \alpha \\
 \text{and} \\
 P\{\text{reject} | P_1, n_1, n_2, C_1, C_2\} &\geq 1 - \beta
 \end{aligned} \quad (10)$$

where $0 \leq C_1 + 1 \leq C_2$, $n_1 - (N - NP_0) \leq C_1 \leq \min\{NP_0, n_1\}$ and $(n_1 + n_2) - (N - NP_0) \leq C_2 \leq \min\{NP_0, n_1 + n_2\}$, an optimal sampling plan (n_1, n_2, C_1, C_2) can be obtained by an exhaustive search for all possible sampling plans.

As a result, the two-stage sampling plan for clinical inspection can be summarized as the following steps:

- Step 1: Given the size of a site subject to clinical inspection, N , set up the AQLs for the two stages, i.e., prespecified C_1 and C_2 that satisfy Eq. 10.
- Step 2: Determine the sample sizes required n_1 and n_2 according to C_1 and C_2 .
- Step 3: Conduct clinical inspection. At the first stage, n_1 subjects (e.g., CRBs) are randomly selected for inspection. If the error (or deficiency) rate is less than C_1/n_1 , then stop the inspection and conclude that the site has passed the inspection; otherwise, proceed to the next stage.
- Step 4: At the second stage, additional n_2 subjects will be randomly selected from the remaining $N - n_1$ subjects for inspection. If the error

(or deficiency) rate is less than $(C_1 + C_2)/(n_1 + n_2)$, the site is considered passing the clinical inspection; otherwise, we conclude that the site has failed clinical inspection.

Note that similarly, the concept of two-stage sampling plan can be extended to a multiple-stage (more than two stages) design for multinational, multicenter clinical trials, especially when there are limited resources available for inspection.

CONCLUDING REMARKS

Clinical inspection is necessary to ensure quality and integrity of the clinical trial conducted for the evaluation of safety and efficacy of a test treatment under investigation. Clinical inspection could be labor intensive and/or time consuming especially when the clinical trial to be inspected is relatively large and involving a number of study sites. In this case, it is suggested that a valid statistical process including sampling plan, acceptance criteria, and testing procedure be adopted for clinical inspection especially when there are limited resources available.

In this article, a simple single-stage sampling plan and a two-stage sampling plan are proposed for clinical inspection. Under the proposed sampling plans, the inspector can prespecify an AQL or a desired inspection accuracy/reliability and then conduct inspection according to the sampling plan for achieving the desired inspection accuracy and reliability. The proposed sampling plans can be applied to clinical inspection for multicenter and/or multinational multicenter clinical trials.

Clinical Pharmacology

Brian Smith

Eli Lilly and Company, Indianapolis, Indiana, U.S.A.

Abstract

Clinical pharmacology is, essentially, the field of medicine whose main interest is the effects of drugs in humans. This entry is focused on breaking down the various areas of clinical pharmacology, which is a field that encompasses a multitude of disciplines.

INTRODUCTION

This area of study is fairly broad. The following excerpt from the introduction to *The Pharmacological Basis of Therapeutics*^[1] gives a glimpse at this field of study: “The clinician is understandably interested mainly in the effects of drugs in man. This emphasis on *clinical pharmacology* is justified, because the effects of drugs are often characterized by significant interspecies variation and because they may be further modified by disease.” From this quote one may define *clinical pharmacology* as the field of medicine whose main interest is the effects of drugs in humans. Within this definition, the field encompasses a multitude of disciplines.

OVERVIEW

A different approach for getting at the heart of clinical pharmacology comes from asking what would be the core curriculum for a training program in this field. In a 1997 issue of *Clinical Pharmacology and Therapeutics*,^[2] knowledge of the following is proposed as a core curriculum in clinical pharmacology and therapeutics for primary care residents:

1. Clinical pharmacokinetics (including drug absorption, distribution, redistribution, clearance and half-life) and its application to patient-based clinical scenarios;
2. Therapeutic drug monitoring;
3. Adverse drug reactions;
4. Drug allergy;
5. Drug–drug interactions;
6. Pharmacokinetics;
7. Prescribing for elderly patients;
8. Prescribing for pediatric patients;
9. Prescribing for pregnant and nursing women;
10. Prescribing for patients with renal disease;
11. Toxicology;

12. Drug regulations applicable to primary care;
13. Bioethical issues and principles related to prescribing;
14. Therapeutic management of common clinical problems, including both drug and nondrug therapies.

This list helps identify the areas that need to be studied by clinical pharmacologists before a new chemical entity can be approved as a drug. Clinical pharmacology is often concerned with the safety, pharmacokinetics, and pharmacodynamics of a new compound. Clinical pharmacology studies are not synonymous with phase I studies. Phase I studies are usually clinical pharmacology studies; however, clinical pharmacology information can often be obtained from studies in other phases of development.

To further classify clinical pharmacology as a discipline, it would be useful to consider the types of clinical pharmacology studies that are performed when a new chemical entity is selected for development. The following list of studies is not meant to be inclusive or a checklist of studies that need to be carried out. It is meant only to give a flavor of clinical pharmacology research.

First Human Dose (Single-Dose Escalation) Studies

These studies are usually open-label, nonrandomized studies performed on healthy volunteers. (If a compound is known to be highly toxic and it is being developed for a life-threatening disease, then often all clinical pharmacology studies are carried out on patients who are not healthy volunteers.) A “no-effect dose,” in units of drug per body weight, is determined from toxicology studies. Then a fraction—say, one-tenth—of this dose becomes the highest that will be allowed in the clinical study. The first dose, which is much less than the maximal dose, is administered to subjects. If no adverse effect is observed, on a later date an increased dose is administered to the subject(s). The increased dose is typically restricted according to some accepted ethics-based algorithm. This is continued for each subject until either a drug-related adverse

event occurs, a drug-related abnormal laboratory value is observed, or the maximal dose is achieved. The primary objective of these studies is safety; however, blood samples and sometimes urine samples are collected to obtain a first glimpse at the compound's pharmacokinetic properties. If a surrogate dynamic or efficacy marker is known, then appropriate tests are carried out to obtain a first glimpse of whether the compound is doing what it is supposed to do.

Multiple-Dose Escalation Studies

These studies are usually open-label, nonrandomized studies performed on healthy volunteers. A maximal dose is chosen from the first study. Then a lower dose is given once or twice a day to each subject for an extended time, which should be sufficient to achieve steady-state systemic concentrations. If no effect is observed, then an increased dose is administered (usually after a washout period). This is continued for each subject until either a drug-related adverse event occurs, a drug-related elevated laboratory value is observed, or the maximal dose is achieved. Again, safety is the primary reason for the study; however, pharmacokinetic and pharmacodynamic information is often obtained.

Fed/Fasted Studies

These studies seek to determine if the pharmacokinetic properties of the compound are affected by food. They are usually a randomized two-period crossover design using healthy volunteers. (If a compound has a long half-life, than parallel designed trials may be more appropriate.)

Drug Interaction Studies

The goal of these studies is to determine if the pharmacokinetics and the pharmacodynamic properties of the compound are affected by another drug. Similarly, they determine if the pharmacokinetic and pharmacodynamic properties of the other drug are affected by the new compound. Randomized three-period crossover designs with healthy volunteers are the norm.

Bioequivalence Studies

These studies seek to determine if the bioavailability of two formulations of the same compound are similar. Again, randomized two-period crossover designs on healthy volunteers are the norm.

Special Population Studies

The goal of these studies is to determine if the pharmacokinetic properties and sometimes pharmacodynamic properties are the same for different groups of people. Population traits studied include gender, race, and disease

types. Special population studies have interpretation problems similar to those of observational studies. This is because, for instance, one cannot randomize an individual to a gender classification.

Absolute Bioavailability Studies

These studies compare the extent of absorption of an oral formulation to the intravenous formulation of a compound. Randomized two-period crossover designs with healthy volunteers are the norm.

Dose Proportionality Studies

A range of doses, on separate occasions, is given to each individual to determine if the compound exhibits "linear" pharmacokinetic properties. Some pharmacokinetic variables (for example, the concentration maximum and the area under the concentration time curve) are related to dose in a proportional manner if the compound exhibits "linear" pharmacokinetic properties. Other pharmacokinetic variables (for example, the plasma clearance and the apparent volume of distribution) are independent of dose if the compound exhibits "linear" pharmacokinetic properties. If the rate of elimination and absorption of a compound into the compartments of a pharmacokinetic model are proportional to the amount in the source compartment, then it is said that the compound exhibits linear pharmacokinetic properties. *Linear*, in this context, is not to be confused with linear models in a statistical context.

Population Pharmacokinetic and Pharmacodynamic Work

In phase II and phase III studies, sparse blood samples are collected from many individuals. With the help of nonlinear mixed-effect modeling, the pharmacokinetic and pharmacodynamic properties of a compound can be explored. One thing often carried out is to relate a pharmacokinetic or pharmacodynamic variable to covariates such as age, disease status, and gender. This work has the same kind of interpretation problems as observational studies.

STATISTICAL DESIGN, METHODS, AND ANALYSIS

Although clinical pharmacology studies are broad in range and scope, many of these studies have enough similarities for common statistical themes.

The designs are often sequential or randomized crossover designs. Period and crossover effects may come into play. It should be pointed out, however, that carryover effects should be easy to eliminate in pharmacokinetic studies. If one knows the half-life of a drug, then one should be able to forecast the amount of time necessary to clear

almost all of the drug, known as the *washout period*. It is not as easy to eliminate carryover effects if the outcome is pharmacodynamic or safety in nature. Period effects, such as carryover effects, are less likely with pharmacokinetic endpoints, but may pose a problem with pharmacodynamic and safety endpoints.

It is not uncommon for the nonrandomized studies discussed to have multiple treatments per subject and repeated measures for each treatment-by-subject combination. The analysis of that data often involves complex mixed-effect models.

The sample sizes are typically small. Sometimes they are chosen for a formal statistical goal; but often they are chosen for nonstatistical reasons, such as cost, or ethical reasons. The small sample size often precludes extensive statistical inferences, particularly where nonsignificant differences exist.

The work is often exploratory in nature. This is especially true for phase I studies. Any clues that could expedite drug development are examined. Undoubtedly, out of the many relationships examined, some will show “statistical significance.” These findings should only be considered hints and not conclusive. Also, the traditional 0.05 significance level should be used judiciously, because of the small sample size. A *p*-value of, say, 0.2 may sometimes be giving evidence of an important effect and should not be ignored. Lastly, the goal of a phase I study often is not hypothesis testing but simply the estimation of a pharmacokinetic or pharmacodynamic variable.

In most clinical pharmacology studies, the null hypothesis of no differences, such as “no safety concern” or “no difference in pharmacokinetic properties,” is the working hypothesis. Rejecting the no-difference hypothesis may be interpreted negatively for the compound. Yet it has been mentioned that these studies are often not formally sized. This may encourage undersizing of the studies. There are three options that could be used to fix this undersizing problem.

The first option is to do a proper power analysis, in which the minimal clinically significant effect is elicited from the clinical pharmacologist or pharmacokineticist.

One problem with this is that if the drug is in early development, notions of variability may be completely unknown. Another problem is that often there will be multiple significance tests performed. Thus there is not always an obvious variable to select for sizing purposes.

The second option can be called a field goal approach: Define an interval of clinically irrelevant differences. Construct a confidence interval for the variable. If the confidence interval (football) falls inside the interval (goalposts), then the hypothesis of no difference holds. This is the type of analysis that is currently performed with bioequivalence studies.

The third approach is similar to the field goal approach but depends on the Bayesian paradigm: Use a noninformative prior for the analysis. Set up an interval of clinically irrelevant differences. Calculate the probability that your statistic falls in that interval. If that probability is sufficiently high (higher than a prespecified threshold), then declare that no difference exists.

The difficulty with all three of these methods is inducing the clinical pharmacologist or the pharmacokineticist to define clinically irrelevant differences a priori.

RECENT DEVELOPMENTS

Two developments in the field are the recently proposed individual and population bioequivalence methods and the recent expectations that population pharmacokinetic and pharmacodynamic work is needed. Discussions of all of these topics can be found as entries in this volume.

Abstract

This article will discuss the concept of the benefit–risk assessment of medicines by decision makers and will provide an overview of key methodology to assess the benefit–risk balance. In addition, it will discuss how health agency and industry regulations are evolving to increase consistency and transparency of the decision-making process.

Keywords: Benefit–risk assessment; Multi-criteria decision analysis; NNT/NNH; Regulatory review; Weight determination.

INTRODUCTION

Regulatory authorities ensure drugs that were granted marketing authorization are high quality, safe, and effective for use in the intended population. As a core part of their drug review process, the regulators assess the benefit–risk (B–R) balance of drugs based on the evidence submitted by the sponsor on efficacy and safety. Regulators determine if the benefits outweigh the risks, in the context of the disease area, other available therapies, and additional factors that can affect the safety and efficacy of the drug.

B–R assessments (BRAs) are complex and involve the evaluation of a large amount of data. The assessment may involve both quantitative analyses and qualitative weighting of the available evidence to access the overall B–R balance of drugs. Over recent years, regulatory authorities including the European Medicines Agency (EMA) and the US Food and Drug Administration (FDA) have reviewed their approaches to BRA and moved to a more structured approach in order to increase the consistency and transparency as well as the communication of the decision-making process.^[1,2]

BRA is not limited to the regulatory review process. For example, sponsor companies continually assess the B–R balance of drugs during the drug development process, and health technology assessment (HTA) authorities may assess B–R balance in the context of a subpopulation, or review different aspects from the regulatory authorities such as patient needs.

In this article, the concept of the BRA of medicines by decision makers is discussed, key initiatives and their outputs are reviewed, structured frameworks and quantitative methodologies to assess the B–R balance are introduced, and finally challenges in the area are discussed.

DEFINITIONS

A “benefit” is the magnitude of a favorable effect (of the drugs) without reference to its probability of occurrence.^[3] The International Council for Harmonisation (ICH) M4E(R2) Guideline emphasizes “key benefits,” which are “favorable effects generally assessed by primary and other clinically important endpoints across the studies in a development program.”^[4] Important product characteristics such as “convenience” dose regimen or administration route that may lead to improved patient compliance and indirect favorable effects such as “vaccine herd immunity” that also affects those other than the patients may be considered as benefits.^[4]

On the other hand, “risk” (in relation to the use of a drug) is a multidimensional concept of the probability of occurrence and the magnitude of any unfavorable effects of the drugs.^[3] Risks relate to the quality, safety, or efficacy of the drugs on patients’ or public health, as well as any undesirable effects on the environment (European Commission (EC) Directive 2001/83/EC).^[5] The ICH M4E(R2) Guideline emphasizes “key risks,” which are “unfavorable effects that are important from a clinical and/or public health perspective in terms of their frequency and/or severity.”^[4]

A BRA is a process comprising many aspects and requires the use of various techniques to establish the B–R balance. The general principles of the BRA of medicines should be based on the available tests and clinical trials carried out on the product designed to test the efficacy and safety, and accounting for the potential impact on the evaluation of benefits and risks through the pharmacovigilance activities (EC Directive 2001/83/EC),^[5] not including economic and other considerations such as “cost-effectiveness” (EC Community Law Regulation 726/2004).^[6] It is noteworthy to acknowledge that there are alternative definitions of BRA outside the regulatory world, such as for HTA.

DECISION MAKERS

Decisions based on the B–R balance of drugs are made by multiple stakeholders throughout the product development process and eventual clinical use (Fig. 1). Specific examples of stakeholders include the following:

- Sponsor internal decision-making portals: decision to develop a drug, to progress from one phase to the next, or to submit for regulatory review
- Regulatory review: initial review, periodic safety updates, and emerging safety issue
- HTA/reimbursement authorities/payers: comparative effectiveness, assessment of subpopulations
- Health-care providers: clinical guidance, resource utilization
- Patient/clinician joint decision-making: ultimately patients make the decision on whether they want to receive a treatment

Fig. 1 Examples of decision makers

Source: Adapted from IMI PROTECT (<http://protectbenefitrisk.eu/index.html>)

These stakeholder groups or individuals may have differing perspectives on the benefits of a medicine or differing tolerance levels for risks. Consequently, these may lead to different views on the B–R balance of a medicine. Increasingly, sponsors, regulators, reimbursement/health-care providers, and clinicians are aiming to ensure patient perspectives on benefits and risks are appropriately considered during the decision-making process.^[7–10]

KEY INITIATIVES

Over recent years, the pharmaceutical industry, government regulatory agencies, HTA authorities, academia, and patient advocacy groups have increased their focus on B–R management. Several initiatives were formed aiming to standardize BRA, to improve transparency, reproducibility, quality, and communication of those assessments. Key initiatives and regulatory activities are described in this section.

Food and Drug Administration

Starting in 2009, the FDA Center for Drug Evaluation and Research (CDER) identified the need for a structured BRA framework to facilitate discussions and improve the communication of the reasoning behind their decision on the B–R balance. The fifth reauthorization of the Prescription Drug User Fees Act 2013–2017 (PDUFA V) in the Food and Drug Administration Safety and Innovation Act further committed the FDA to implement a structured B–R (sB/R) framework in the FDA’s review templates.^[1] (See FDA BRAF framework.)

The FDA CDER developed a qualitative sB/R framework through an extensive review and analysis of previous and ongoing regulatory decisions. They planned a staged approach to the implementation of the sB/R framework in order to allow opportunity for continual refinement. In 2015, the FDA implemented the framework for new molecular entity and original biologics license application (BLA) with the eventual aim of expanding its use to all new drug applications by fiscal year 2017.^[1]

The current FDA sB/R framework does not explicitly incorporate patient perspectives on benefit and risks. The 21st Century Cures Act, enacted into US law in December of 2016, importantly considers patient-focused drug development and requires the FDA to establish a structured BRA framework where patient experience data may be considered.^[8] Furthermore, the sixth reauthorization of the PDUFA (PDUFA VI, 2018–2022) aims to strengthen efforts to incorporate patient perspectives into the drug development and review process, and advances the use of a structured approach to inform regulatory decisions on whether the benefits of a medicine outweigh its risks.^[11]

Since 2012, the FDA Centers for Devices and Radiological Health (CDRH) have examined ways to incorporate

the patient perspectives into the B–R decision-making process on medical devices. Their guidance document, issued in 2016, “Factors to Consider When Making Benefit-Risk Determinations in Medical Device Premarket Approvals and De Novo Classifications” highlighted the importance of considering the patient perspectives on what constitutes a meaningful benefit and their tolerance levels to risk within the BRA of devices.^[7] A companion guidance document on patient preference information (PPI) was issued in parallel—explaining the concepts that sponsors and other stakeholders should consider when choosing to collect PPI, which may inform FDA’s B–R determinations.^[12] The CDRH is a member of the Medical Device Innovation Consortium (MDIC), a nonprofit public–private partnership. In 2015, the MDIC Patient Centered Benefit-Risk (PCBR) issued a Framework Report. The Framework Report includes a catalog, which provides an overview of a range of available patient preference methods.^[12] These patient preference methods are defined in the PCBR Framework Report as “Patient preference methods are methods for collecting and analyzing data that allow quantitative assessments of the relative desirability or acceptability to patients of attributes that differ among alternative medical treatment approaches.”^[13]

European Medicines Agency

Started in 2009, the 3-year EMA B–R project aimed to “enhance the transparency of the B–R decision-making process, and facilitate the communication of the rationale for each decision, both within the regulatory system and to the public.”^[14] The project focused initially on researching the current practice of BRA in regulatory agencies in the European Union, developing and testing tools for BRA, with the final phase of the project being training and implementation phase (started in 2012).^[2] One of the recommendations of the project was the use of the Effects Table as a tool to summarize the key benefits and risks.^[14] The Effects Table subsequently was implemented by the EMA in the Rapporteur’s Day 80 assessment report template and is updated throughout the assessment until the Day 210 report and eventual inclusion in the European Public Assessment Report (EPAR). (For an example, see the “EMA Effects Table” section.)

International Council for Harmonisation

The ICH recently updated two guidance documents relating to BRA, intending to set a common standard among the ICH regions. The ICH guidance E2C(R2) Periodic Benefit-Risk Evaluation Report (PBRER), adopted from November 2012, expanded the concept of the PSUR (Periodic Safety Update Report) from an interval safety report to a cumulative B–R report. Section 3.18 of the PBRER should provide an “integrated and critical analysis of the key information” in the BRA.^[15]

With the emphasis on providing greater structure for BRA in regulatory decision-making, ICH revised their guidance on the Common Technical Document (CTD) Section 2.5.6 “Benefits and Risks Conclusions” in M4E(R2), adopted in June 2016. Section 2.5.6 of the CTD should “provide a succinct, integrated, and clearly explained benefit-risk assessment of the medicinal product for its intended use.”^[4]

CIRS UMBRA Initiative

In 2012, the Centre for Innovation in Regulatory Science (CIRS) formed the “Unified Methodologies for Benefit-Risk Assessment” (UMBRA) initiative, consolidating various activities in the field of BRA with the aim to provide “a single platform for the development, assessment, implementation and ongoing refinement of an internationally acceptable, structured, systematic, standardized approach to the benefit-risk assessment of medicines.”^[16] Initiatives consolidated under the UMBRA initiative included Pharmaceutical Research and Manufacturers of America (PhRMA) Benefit-Risk Action Team (BRAT), which initiated in 2006 and developed the PhRMA-BRAT framework,^[17,18] which was later renamed as CIRS-BRAT (see the “Framework” section).

Innovative Medicines Initiative and European Federation of Pharmaceutical Industries and Associations

The IMI-PROTECT is the Pharmacoepidemiological Research on Outcomes of Therapeutics by a European Consortium (PROTECT) program funded by the Innovative Medicines Initiative (IMI) Joint Undertaking between the European Union and the pharmaceutical industry association European Federation of Pharmaceutical Industries and Associations (EFPIA), coordinated by the EMA. The IMI-PROTECT Benefit-Risk group specifically focused on structured methodologies for B–R integration and representation (<http://protectbenefitrisk.eu>).^[19] They conducted a systematic review of BRA methodologies^[20] and proposed candidate methodologies for testing in several case studies.^[21] The final report provides recommendations for BRA methods and visual representation including a five-stage guidance “roadmap.”^[22,23] Preliminary research was also conducted in “patient and public involvement” in BRA, with a focus on testing preference elicitation methods, assessing the preference and understanding of visual display formats, and ways to communicate the B–R balance.^[24]

IMI ADVANCE (Accelerated Development of Vaccine Benefit-Risk Collaboration in Europe) project was launched in December 2013 to build a pan-European framework for rapidly assessing and communicating the benefits and risks of vaccines. Several white papers and code of conduct for B–R monitoring and assessment of vaccines have been published, including near real-time BRA using multinational health-care databases.^[25]

IMI PREFER (Patient Preferences in Benefit-Risk Assessments during the Drug Life Cycle) officially started in October 2016. It is part of the second phase of IMI including partners representing patient organizations and clinical research, HTA bodies, and industries. The aim of the project is to establish recommendations to support the development of guidelines on how and when to include patient perspectives on benefits and risks of medicinal products.^[26]

ISPOR Risk-Benefit Management Working Group

The International Society for Pharmacoeconomics and Outcomes Research (ISPOR) established the Risk-Benefit Management Working Group in 2005 with a focus on the methodology for BRA. They subsequently published a comprehensive systematic literature review to identify quantitative methodologies for BRA.^[27] The ISPOR Good Practices for Outcomes Research reports (www.ispor.org/workpaper/practices_index.asp) also include useful guidance recommendations for conducting research relevant for BRA (including multi-criteria decision analysis and conjoint analysis).^[28–30]

EFSPI Benefit-Risk Special Interest Group and QSPI Benefit-Risk Working Group

Due to the technical nature of the structured quantitative BRA, it is inevitable that many statisticians are at the forefront of the scientific advancement of the area. Two B–R statistical special interest/working groups (BRSIG/BRWG) were established under the auspices of the European Federation of Statisticians in the Pharmaceutical Industry (EFSPI), and the Society of Clinical Trials/Quantitative Sciences in the Pharmaceutical Industry (SCT/QSPI) in the United States, respectively. Although the ultimate goals of these two B–R working groups are similar,^[31,32] i.e., to promote and enhance quantitative BRA methodologies from statistical standpoints, EFSPi BRSIG focuses on the Europe efforts, whilst QSPI BRWG focuses on the US efforts. Both groups exchange the knowledge on a regular basis to keep each other up to date. The outputs from the EFSPi BRSIG and QSPI BRWG include newsletters, review articles,^[33] a book,^[34] and an internet blog (www.benefit-risk-assessment.com/).^[35]

STRUCTURING BRAS

Frameworks

Frameworks are structured step-by-step guides as to how to conduct BRAs. The frameworks aim to aid the decision-making process by establishing a standardized approach, and thereby increasing consistency, transparency in the decision-making process, and subsequently facilitating the communication of the decision.

Five frameworks emerging from the key initiatives are described in this section. Although the frameworks differ in the number of steps and the details contained within, many contain common elements: clearly define the decision problem including the target population and treatment alternatives, identify the key benefits and risks, identify the sources of data (including the clinical trials results), assess the (relative) importance of the key benefits and risks, evaluate uncertainty, summarize the data, and interpret the results.

Nixon^[36] provides a side-by-side comparison of the ProACT-URL and BRAT frameworks and concludes, “Although the two frameworks BRAT and ProACT-URL differ in their details, the common roots of the methods lead them to being essentially the same.”

ProACT-URL

ProACT-URL was first introduced by John Hammond, Ralph Keeney, and Howard Raiffa as a stepwise approach to making effective decisions.^[37] The essence is to divide and conquer—even the most complex—decision problems in eight steps. The ProACT steps remind decision makers that best decisions are the ones made proactively, and the remaining steps help to reflect and clarify the decisions in volatile and evolving environments.^[37] The URL steps reflects the uncertainty and risk faced by decision makers. A feature of ProACT-URL is the use of an *Effects Table* to represent the key drivers of the BRA, which has subsequently been recommended by the EMA (EMA/90842/2015 Section 5. Benefit risk assessment—Effects Table).^[38]

The EMA Benefit-Risk Working Group developed an adaptation of Hammond’s ProACT-URL approach to improve the EMA’s assessment of benefits and risks of medicines. They expanded ProACT-URL to be more specific to the Agency’s needs.^[39] The eight steps of the ProACT-URL for use in drug BRA are summarized in Fig. 2.

EMA Effects Table

Following the EMA Benefit-Risk Working Group adaptation of ProACT-URL for drug BRA, they subsequently recommended the use of an Effects Table for Day 80 critical assessment report.^[38] An Effects Table is a compact and consistent tabular presentation of the key benefits and risks data considered in the decision-making process, which should be used for new marketing applications and important extensions of indication applications. Figure 3 shows the proposed structure of the EMA Effects Table, which is a living document that would be included in the Regulatory Rapporteur’s Day 80 report and is updated for Day 120 List of Questions and for the Committee on Human Medicinal Products Day 210 report, and subsequently included in the EPAR. Further discussions on Effects Table are available on www.benefit-risk-assessment.com/.^[35]

Problem	Determine the nature of the problem and its context
	Frame the problem
Objective	Establish objectives that indicate the overall purposes to be achieved
	Identify criteria for (a) favourable effects, and (b) unfavourable effects
Alternatives	Identify the options to be evaluated against the criteria
Consequences	Describe how the alternatives perform for each criterion, i.e., the magnitudes of effects, and their desirability or severity, and incidence
Trade-off	Assess the balance between favourable and unfavourable effects
Uncertainty	Report the uncertainty associated with the favourable and unfavourable effects
	Consider how the balance between favourable and unfavourable effects is affected by uncertainty
Risk tolerance	Judge the relative importance of the decision maker's risk attitude for the product
	Report how this affected the benefit-risk balance
Linked decisions	Consider the consistency of this decision with similar past decisions, and assess whether taking this decision could impact future decisions

Fig. 2 PrOACT-URL for drug BRA

Effect	Short description	Unit	Treatment	Control	Uncertainties/ Strength of evidence	References
Favourable effects (key benefits)						
Unfavourable effects (key risks)						

Fig. 3 EMA Effects Table
Source: From <http://www.benefit-risk-assessment.com/>.^[35]

BRAT Framework

The BRAT framework, originally developed by PhRMA, comprises processes and tools to improve BRA by enhancing the transparency, reproducibility, and communication of the B–R balance.^[17,18] In 2012, the work of PhRMA-BRAT was transitioned to the CIRS and renamed CIRS-BRAT. The CIRS-BRAT tool and User Guides are available for download at www.cirs-brat.org and include a tutorial of B–R analysis within the Framework User Guide.

The framework comprises a six-step process: (i) define the decision context, (ii) select benefit and risk outcomes,

(iii) identify and extract source data, (vi) customize the framework, (v) assess outcome importance, and (vi) display and interpret key B–R measures.^[17,18]

FDA sB/R Framework

The sB/R framework is a 5 × 3 grid that FDA’s reviewers populate with a clear description of key B–R determinations, including an analysis of the condition, current treatment options, benefits, risks, and measures to minimize potential safety concerns. The framework aims to clarify how FDA reaches the final regulatory decision in a

succinct summary. Like the EMA Effects Table, the FDA sB/R Framework is also a living document. Figure 4 shows a blank template for FDA.

Quantitative Methodologies

Quantitative methodologies can be useful to aid decision makers when exploring the B–R balance, particularly where there are multiple criteria to be considered or conflicting viewpoints on the importance or relevance of these criteria from different stakeholders.^[39] Quantitative methodology may also make explicit the use of views from stakeholder groups or individuals by formally incorporating data on preferences in order to assess the B–R balance. It is important to note that the aim of quantitative methodology in BRA is not to replace the qualitative expert judgment but to aid the decision-making process.^[40]

The ISPOR Risk-Benefit Management Working Group, EMA Benefit-Risk methodology project, and IMI-PROTECT performed literature reviews of the available methodologies and provided the details of several quantitative methodologies with potential application in BRA, including MCDA and stochastic multi-attribute acceptability analysis (SMAA), and quantitative measures including number needed to treat (NNT), number needed to harm (NNH), impact numbers, incremental net health benefit, and benefit:risk ratio. For further reading on the available methodology, the final review papers from the three initiatives are recommended.^[20,27,41]

Here, the quantitative measures NNT/NNH and the quantitative methodology MCDA are described in the context of BRA.

Number Needed to Treat/Number Needed to Harm

NNT refers to the average number of patients who need to be treated with a given treatment to prevent one additional event compared with a control therapy or no treatment.^[42] Let p_1 and p_2 denote the proportion of patients with an

event in the control and treatment group, respectively, and the NNT is defined as

$$\text{NNT} = 1/(p_1 - p_2).$$

Preventing the event used to evaluate the efficacy of a treatment is a benefit event. NNT is considered a useful measure of clinical benefit, being intuitive and interpretable.^[42–44]

Similarly, this measurement can be used to evaluate the risk and usually is termed as the number needed to harm (NNH). Specifically, the NNH is calculated as

$$\text{NNH} = 1/(q_2 - q_1)$$

where q_1 and q_2 are the incidence rates of an adverse event (AE) in the control and treatment groups, respectively. NNH is interpreted as the number of patients who need to be treated to cause one more AE compared with a control therapy or no treatment.

In the case where a single benefit and a risk can be identified in BRA, NNT and NNH can be the useful and simple methods to provide an overall balancing of benefit and risk. For example, AE-adjusted NNT (AE-NNT) estimates the number of patients needed to treat to prevent one additional event without inducing treatment-related AEs compared with the control.^[45] AE-NNT is useful for a situation where there is only one AE of interest, and the benefit event and AE are independent.

The overall BRA can be performed through a comparison of NNH and NNT using the ratio $r = \text{NNH}/\text{NNT}$. This ratio refers to the number of benefit events prevented for each AE caused by treatment on average. A favorable B–R profile may be concluded if the ratio is >1 . One weakness of this approach is that the relative importance of the AE to the benefit is not incorporated, which may imply that the benefit and risk are of the same importance. However, a threshold C_r can be set for the ratio to claim that the benefit outweighs the risk when $r > C_r$, where the value of C_r depends on the relative clinical importance of the benefit and AE. The relative importance or relative weight of the benefit and risk can also be incorporated into the calculation of NNH and NNT as an adjusted ratio.^[46]

To evaluate the uncertainties in the ratio of NNH and NNT, a confidence interval (CI) can be constructed. The ratio can be expressed as

$$\hat{r} = \frac{\hat{q}_2 - \hat{q}_1}{\hat{p}_1 - \hat{p}_2} = \frac{\Delta \hat{q}}{\Delta \hat{p}}.$$

A delta method can be applied to derive the variance estimate for $\hat{r}$:

$$\hat{v}(\hat{r}) = \hat{r}^2 \left[\frac{\hat{v}(\Delta \hat{q})}{\Delta \hat{q}^2} + \frac{\hat{v}(\Delta \hat{p})}{\Delta \hat{p}^2} - 2 \frac{\text{cov}(\Delta \hat{q}, \Delta \hat{p})}{\Delta \hat{q} \Delta \hat{p}} \right]$$

Source: From Draft PDUFA V Implementation Plan.^[1]

Assuming the normal approximation, a Wald-type CI for r can be constructed. However, in general, the normal approximation may not always work well and the ratio could be heavy-tailed or bimodal.^[47] This CI may also be problematic when either NNH or NNT is not significantly greater than zero. As an alternative, a bootstrapping approach can be used to construct the CI. The issue with the construction of CIs is similar to that for NNT. Altman^[48] provides a way to interpret the CI for NNT that crosses zero. Refer to the work of Ke and Jiang^[49] for more discussions on the CI for the NNH-to-NNT ratio.

NNT has been extended to a survival endpoint.^[49–52] The ratio of NNH and NNT can be evaluated in a similar fashion. Ke and Jiang^[49] proposed a general semiparametric additive hazards model to estimate NNT and the ratio of NNH and NNT for use in BRA.

As an example, He^[53] described the use of NNT and NNH in evaluating the B–R balance of vorapaxar, an oral antiplatelet agent, versus a placebo on the background of standard of care in the secondary prevention of atherothrombotic events in patients who had a history of myocardial infarction, ischemic stroke, or peripheral arterial disease. CV death (efficacy) and fatal bleeding (safety) are the important benefit and risk endpoints. The exposure-adjusted NNT and NNH for vorapaxar was 918 patient years and 2971 patient years compared with placebo for CV death and fatal bleeding, respectively. Therefore, treatment with vorapaxar plus standard of care in 918 patient years may prevent one CV death, whereas treatment with vorapaxar plus standard of care in 2971 patients may cause one fatal bleeding. The ratio of NNH to NNT is 17, indicating that one fatal bleeding would be caused for every 17 CV deaths prevented by vorapaxar. Based on the results, and a favorable balance observed during the analysis of other key benefits and risks, it was concluded that vorapaxar plus standard of care demonstrated a favorable B–R profile compared to the standard of care alone.

Multi-Decision Criteria Analysis

MCDA originates from decision theory and allows for the consideration of multi-attributed decision outcomes,^[54] thereby fitting for use in the assessment of the B–R balance

of a medicine, where multiple benefit and risk criteria may be considered.^[55]

The MCDA was defined by Keeney and Raiffa as “an extension of decision theory that covers any decision with multiple objectives. A methodology for appraising alternatives on individual, often conflicting criteria, and combining them into one overall appraisal....”^[54] Other broader definitions exist such as the approach taken by ISPOR MCDA Good Practices Task Force, which includes “partial” MCDA techniques where “...including in our consideration of MCDA methods that help deliberative discussions using explicitly defined criteria, but without quantitative modeling.”^[28] Here, we consider Keeney–Raiffa’s approach, using MCDA to provide an overall quantitative assessment of B–R balance and thereby enabling simultaneous comparison of multiple outcomes for two or more treatment options. We describe the weighted sum model (WSM) approach to MCDA using the value function method, which is a common approach used.^[39]

MCDA follows a structured stepwise approach, with the initial steps (Fig. 5) essentially in line with the broader decision-making frameworks previously described (see the “Frameworks” section). At a high level, the steps involve breaking the problem into smaller components once the decision context has been set: identifying the B–R criteria to evaluate the treatment alternatives, transforming the data into a standardized unit (using value functions), scoring the data, directly comparing the criteria (weighting), and finally aggregating the individual criteria into an overall assessment.

The criteria are often structured visually into a hierarchical value tree (see the “Visualization” section), to group criteria and aid selection of the final criteria that reflect the value of each treatment option (i.e., the key benefits and risks).

The next steps of the MCDA (Fig. 6) bring together the multiple criteria using a common unit: scoring the data (or performance), assessing the relative importance of the criteria (weighting), and finally calculating the overall score for each treatment option. The scoring and weighting steps involve subjective judgment by the relevant stakeholders (or decision makers).

Score Performance: Partial value functions are constructed for each B–R criterion and used to obtain

Fig. 5 Initial steps of MCDA: In line with broader decision-making framework

Fig. 6 Next steps of MCDA: Bring together multiple criteria

performance scores based on the clinical trials data (see Fig. 7). They represent a stakeholder's judged value in the performance of a treatment option across the plausible levels within a criterion. These partial value functions are essentially standardized scales across all criteria. Linear partial value functions (e.g., Fig. 7a) that assumes equal judged value per unit change in the level within a criterion are often used, although nonlinear functions (e.g., Fig. 7b) such as step or exponential may also be considered.

The partial value functions are often bounded by a lower value that represents the worst plausible outcome and an upper value that represents the best plausible outcome. The choice of the plausible values may be the range of possible observed values for an endpoint within the clinical trial data (e.g., systolic blood pressure: a minimum plausible value of 70 mmHg and a maximum plausible value of 270 mmHg). When bounded by 0 and 100, the value “100” represents the most preferred score and “0” represents the least preferred score, based on the mapped plausible outcome values. The partial value functions represent not only the ordering of preferences but also the strength of preferences for changes within each criterion. For further reading on value functions, see the work of Belton and Stewart.^[39]

Weighting: This step assesses the relative importance *between* the criteria. Swing weighting method can be used to define the trade-off that the stakeholder will make

between criteria (for details, see the work of Mussen^[56]). The stakeholder judges the weights to be allocated to each criterion, with the weights ω_i representing the relative importance of the “swing” from the worst plausible value to the best plausible value in the i th criterion. Weights are assigned based on the criteria alone, independent of treatment. The weights can then be normalized across criteria so the total sum of all weights equals 100, but preserving the ratios between the weights.

Methodology for constructing partial value functions and preference weights is not described in detail here, including the elicitation methods. For further reading, see the works of Keeney and Raiffa^[54] and Belton and Stewart,^[39] and also Hockley^[26] for recommendations on elicitation methods for the patient and public involvement specific for BRA of medicines.

Calculate overall score: In the final step, the partial value functions are combined into an overall score, taking into account the relative importance (weights) of the criteria. Assuming an additive model, the overall score is calculated using the weighted sum approach. Weighted score can be calculated separately for the benefits and for the risks, and overall for the benefits and risks combined.

For a given treatment a , let $v_i(a_i)$ represent its performance score for criterion i , and ω_i represent the weight for each criterion i . Then, for n criteria, the overall weighted B–R score is given by

Fig. 7 Examples of partial value functions

$$V(a_i) = \sum_{i=1}^n \omega_i v_i(a_i)$$

where $\sum_{i=1}^n \omega_i = 100$

The overall B–R score and the contribution of each individual criteria can be displayed graphically, e.g., using stacked bar charts (see the “Visualization” section), which can aid in the reporting and interpretation of results.

The WSM MCDA approach described here requires several assumptions regarding the criteria, and their weights, including additive independence, preference independence of criteria, value independence, and the need for the weights to satisfy the trade-off requirements.

Sensitivity analysis is required to assess the robustness of the overall B–R score to changes in the shape of the value function, scores, weights, and input data, and to understand the effects of all sources of uncertainty. Broekhuizen^[57] performed a literature review of how uncertainty can be explicitly taken into account in MCDA and concluded that deterministic sensitivity analysis is most likely suitable for most health-care policy decisions.

For an example of MCDA used in the regulatory setting, see the work of Marcelon,^[58] for details of the development of the MCDA model, and EMA/415775/2014^[59] for the EMA Assessment Report. For a literature review of health-care MCDAs, see the work of Marsh,^[60] and for a detailed discussion of application of MCDA for HTA, see the work of Thokala.^[61]

General Methods to Deal with Uncertainties

With much increased emphasis from regulatory agencies, industry, and the medical community on the efforts to further enhance structured BRA and improving transparency, consistency, and communication, uncertainty has been recognized as a key issue in BRA. The FDA has highlighted the importance of evaluating the uncertainty related to BRA through its structured B–R framework,^[1] including how to translate the BRA from premarket to postmarket. EMA indicated that a quantitative model could be useful to explore the impact of uncertainty related to BRA, while judgment plays a key role in BRA.^[55]

Identifying and addressing uncertainties is critical for BRA. Uncertainty could come from many aspects of BRA, such as sources, timing, and nature of information available throughout a drug’s life cycle.^[62] Some uncertainties could be considered known such as efficacy estimates from clinical trials; some uncertainties are unknown unknowns such as AEs with low frequency that may not be well understood in clinical trials; and some uncertainties are unknown unknowns such as a very rare safety event, which may only emerge in the postmarketing setting. Our understanding is that there are three major sources for uncertainties, which could be associated with the level of evidence

for benefits and risks in clinical development, respectively; associated with the relative importance of benefits versus risks; or associated with translation of BRA from a premarket to a postmarket setting.^[63,64]

Not all of the uncertainties can be quantified and addressed. To quantify or account for the uncertainties, we identify the source for the uncertainties first and then come up with ways to address these uncertainties.^[63,64] CIs and visualization tools could be useful to highlight the uncertainties related to the level of evidence for benefits and risks. Sensitivity analyses of weight selection are critical to evaluate the uncertainties related to the relative importance of benefits versus risks. Weights can be fixed or random, and the B–R decision can be based on the methods that incorporate the uncertainty of weighting, e.g., SMAA.^[65] In addition, continuous ongoing BRA, risk management plan, postmarket safety and efficacy studies, etc., are important to mitigate the uncertainties associated with the translation of BRA from a premarket to a postmarket setting.^[66]

In addition to the sources of uncertainties described above, there are a few other sources. For example, if a clinical event is included in both the efficacy and safety endpoints, this endpoint definition could lead to these events being counted twice in BRA. Double counting could also occur if a serious adverse reaction is identified as an important safety endpoint and malignancy is cited as a separate safety endpoint for BRA. One approach is to conduct sensitivity analysis using endpoints that do not overlap. Evaluation of uncertainties related to BRA is critical and challenging. The decision-making could be complicated. While qualitative thinking is the focus, quantitative approaches could be helpful. It is important to consider all of the relevant aspects including context matters, sources of uncertainties (clinical, methodological, and statistical) matters, and operational challenges.^[62]

Visualization

Appropriate use of visual representations not only succinctly summarize the information on B–R balance but may also contribute to better perception and may trigger advantageous emotional response.^[67] Regulators may have different perception of B–R balance depending on their gender, length of experience, and cultural background.^[68] By capitalizing on the structured quantitative BRA methodologies and effective visual displays, decision makers may control these affective factors to assure that conflicting perceptions and emotions do not dominate decisions.^[69]

However, the use of visual displays in regulatory decision-making is still lacking, but the paradigm has shifted toward being more inclusive of visual displays when communicating B–R information. A key review commissioned by the FDA acknowledged that it is not necessary to prescribe specific visual display formats for all circumstances and concluded that “no single specific format, structure, or

graphical approach emerged as consistently superior.”^[70] Additionally, numeric B–R presentation had a positive impact on several outcomes when compared to non-numeric presentation. Consequently, visual displays that present both graphical and numeric B–R information would be of better value—so long as the visual displays are not exhaustive and well designed.^[71,72] The common visual representation of benefits and risks include effects tables, tree diagrams, forest plots, and bar graphs. More examples of visual representations in BRA are available in the literature.^[23,70]

Effects Table

There are various proposals on how to create a table to present the technical information in a BRA of drugs in a regulatory setting. An exemplary use of such a table is by the EMA, which is known as an Effects Table^[38] (Fig. 3)—also see the “EMA Effects Table” section. A structured table like an Effects Table provides an increased level of clarity, consistency, and transparency to facilitate the assessment of key benefits and key risks that contribute to the current regulatory decision.

Tree Diagrams

A tree diagram is a hierarchical structure that looks like a “tree,” commonly inverted on its side, as shown in Fig. 8. It is an explicit visual map that groups associated outcomes or criteria together to assist decision makers to be more open about the selection and nonselection of any particular outcome for the current decision problem.^[69] There is not a consensus on how best to construct a tree diagram, but it is seen as an iterative process of *growing* and *pruning* the tree until all outcomes that matter have been included.

In BRA, particularly in relation to the MCDA (see the “Multi-Decision Criteria Analysis” section), tree diagrams are commonly referred to as *value tree* or *effects tree diagrams*. They are borne out of a specific context and/or a methodology^[69] and are also customizable.^[17] Value/effects tree diagrams are particularly useful at the beginning of a

Fig. 8 An example of a tree diagram assessing the B–R balance of treatment options for acute exacerbation chronic bronchitis
 Source: Data from IMI PROTECT telithromycin case study. Quartey, G. 2012.^[21]

BRA during the planning stage, and then fine-tuned with respect to the available evidence.^[22]

Forest Plots

A forest plot (or an interval plot) can be useful to display several benefit and risk outcomes in one graphical summary to allow for a “side-by-side” comparison. An example of a forest/interval plot is shown in Fig. 9.

A forest or interval plot contains the point estimate and the associated uncertainty of several outcomes. In the example, the point estimate is the rate difference of two treatments and depicted as dots for each benefit and risk outcome. The bars represent the associated 95% CIs, with additional color-coded as the benefit or risk criteria. The plot is flexible to accommodate other measures such as odds ratios and means. However, because of a single axis, every outcome on a forest/interval plot must be presented in the same unit.

Bar Graphs

A bar graph, or a bar chart, is a common visual representation method for categorical data. The height (or length in the case of a horizontal bar graph) of the bars represents the quantitative information. For example, Fig. 10 shows the stacked bars of different risk outcomes by treatment. Each colored bar represents the rates per 1000 patients for each risk outcome, e.g., 5/1000 patients of cardiac events for treatment B, measured from the bottom to the top of the lilac-colored bar on the right. The color scheme is chosen from the Color Advice for Cartography website (<http://colorbrewer2.org/>).

There are many various other forms of bar graph,^[23] including the histogram that carries information in both the height and width of the bars. Stacked bar graphs are often found useful in a BRA to represent multiple B–R outcomes being considered. In particular, a single stacked bar graph can easily accommodate quantitative benefit and risk data measured in the same units using the value-based B–R methods such as MCDA and SMAA. The overall height of the bar would subsequently represent the total B–R value score of that treatment option that can be used to rank the overall B–R balance to support decision-making.

CHALLENGES

Challenges with BRA have been well recognized (see the work of Guo^[27] and EMA/297405/2012^[55]). It involves multifactorial sources of evidence and is informed by science, medicine, and policy (FDA PDUFA V^[11]). Human judgment, which is unavoidably subjective, plays an essential role in BRA as data and models do not make a decision. Despite many efforts from regulatory,

Source: Data from IMI PROTECT telithromycin case study. Quartey, G. 2012.^[21]

In addition, there may not be sufficient data or evidence for a BRA. The drug development process has been centered around the evidence for efficacy, and thus, safety information in the premarket BRA is not specifically targeted with potentially short follow-up duration to understand long-term risk or risk for rare events. On the other hand, during postmarket BRA, no or little efficacy evidence continued to be collected, and large amount of safety data are usually collected in an observational fashion. A drug development strategy targeting evidence generation for BRA should be recommended. There is also limitation of access to data for competing treatment.

CONCLUSION

BRA is receiving increased attention across all stages of clinical research including product development, regulatory assessment, and HTA. Several initiatives have looked and continue to look at how to improve the transparency and consistency of the decision-making process, as well as how to best capture and incorporate patient preferences in the decision-making process. Methodologies are emerging for use in clinical research to aid the decision-making process—including framework and quantitative methods such as NNT/NNH and MCDA described here.

Challenges exist in the implementation and the acceptability of quantitative methodology, but increased focus on quantifying patient opinion may lend itself to more quantitative methodology. Alongside the framework, structured quantitative methods can aid discussions and increase transparency of the BRA with well-designed visual representations and appropriate sensitivity analysis.

academia, and industry, there is no widely accepted approach to BRA.

To apply quantitative methods to BRA, it is necessary to incorporate values of benefits and risks, e.g., through weighting. Whose values should be included is not clear. Different stakeholders, including sponsors, regulators, payers, and individual physicians, patients, and caregivers, may all have different views on the values. While patients actually use the medical products, their perspectives are not typically included in the BRA. There have been some efforts quantifying the values of patients or experts, but this has not been done systematically and is usually done outside the clinical trials.

Abstract

In most clinical trials comparing a test drug and a control treatment effect is usually established by comparing mean response change from baseline of some primary study endpoints assuming that their corresponding variabilities are comparable. This entry gives several methods of comparing variabilities and explores how to analyze the results.

INTRODUCTION

In most clinical trials comparing a test drug and a control (e.g., a placebo control or an active control), treatment effect is usually established by comparing mean response change from baseline of some primary study endpoints assuming that their corresponding variabilities are comparable. In practice, however, variabilities associated with the test drug and the control could be very different. When the variability of the test drug is much larger than that of the reference drug, safety of the test drug could be a concern. Thus, in addition to comparing mean responses between treatments, it is also of interest to compare the variabilities associated with the responses between treatments.

In practice, the variabilities associated with the response are usually classified into two categories, namely, the intrasubject (or within-subject) variability and the intersubject (or between-subjects) variability. Intrasubject variability refers to the variability observed from repeated measurements from the same subject under the same experimental condition. On the other hand, intersubject variability is the variability due to the heterogeneity among subjects. The total variability is simply the sum of the intra- and intersubject variabilities. In practice, it is of interest to test for equality, noninferiority/superiority, and similarity (or equivalence) between treatments in terms of the intrasubject, intersubject, and/or total variabilities. Under a replicated parallel design, the usual F -test can be performed to compare intrasubject variabilities. Under a replicated crossover design, Chinchilli and Esinhart^[1] proposed the F -test using an orthogonal transformation to test for difference in intrasubject variability between treatments. Under replicated parallel designs, however, intersubject and total variabilities between two treatments cannot be compared by the usual F -test because the distribution of

estimators does not follow a chi-square distribution. In these cases, the modified large sample (MLS) method is suggested (see, e.g., Refs.[2–5]). The MLS method is shown to be superior to the other approximation methods in practice. Under a replicated crossover design, the MLS method is not appropriate to compare intersubject and total variabilities because estimators of variance components are not independent. Lee et al.^[6] extend the MLS method when estimators of variance components are dependent. In addition, Lee et al.^[7] study a test for comparing intersubject and total variabilities under replicated crossover designs based on the extension of the MLS method.

In practice, instead of comparing intrasubject variabilities, it may be of interest to compare intrasubject coefficient of variation (CV). In recent years, the use of intrasubject CV has become popular when assessing the reproducibility, similarity, and stability of a drug product when the drug product is repeatedly administered over a period of time. In this entry, we will discuss two statistical methods by Chow and Tse^[8] and Quan and Shih.^[9]

OVERVIEW

In the next four sections, statistical tests for equality, superiority/noninferiority, and similarity under a crossover design or a parallel design in clinical trials are derived for comparing intrasubject variability, intrasubject CV, intersubject variabilities, and total variabilities, respectively. The section “Sample Size Calculation” provides formulas for sample size calculation corresponding to respective statistical tests. Some concluding remarks are given in the last section. Throughout this article, for the sake of convenience, we will denote test formulation (drug) and reference formulation (drug) by T and R, respectively.

COMPARING INTRASUBJECT VARIABILITIES

To assess intrasubject variability, replicates from the same subject are necessarily obtained. For this purpose, replicated crossover designs or parallel group designs with replicates are commonly employed. In what follows, statistical tests for comparing intrasubject variabilities under a parallel design with replicates and a replicated crossover design (e.g., a $2 \times 2m$ replicated crossover design) will be studied.

Parallel Design with Replicates

Let x_{ijk} be the observation of the k th replicate ($k = 1, \dots, m$) of the j th subject ($j = 1, \dots, n_i$) from the i th treatment ($i = T, R$). The following linear mixed effects model is usually considered:

$$x_{ijk} = \mu_i + S_{ij} + e_{ijk} \quad (1)$$

where μ_i is the treatment effect, S_{ij} is the random effect due to the j th subject in the i th treatment group, and e_{ijk} is the intrasubject variability under the i th treatment. It is assumed that for a fixed i , S_{ij} is independent and identically distributed as a normal random variable with mean 0 and variance $\sigma_{B_i}^2$, and e_{ijk} , $k = 1, \dots, m$ is independent and identically distributed as a normal random variable with mean 0 and variance $\sigma_{w_i}^2$. Under this model, an unbiased estimator for intrasubject variance $\sigma_{w_i}^2$ is given by

$$\hat{\sigma}_{w_i}^2 = \frac{1}{n_i(m-1)} \sum_{j=1}^{n_i} \sum_{k=1}^m (x_{ijk} - \bar{x}_{ij.})^2 \quad (2)$$

where

$$\bar{x}_{ij.} = \frac{1}{m} \sum_{k=1}^m x_{ijk} \quad (3)$$

It can be seen that $n_i(m-1)\hat{\sigma}_{w_i}^2/\sigma_{w_i}^2$ is distributed as a χ^2 -distribution with $n_i(m-1)$ degrees of freedom. Note that $\sigma_{w_T}^2$ and $\sigma_{w_R}^2$ are intrasubject variances for test and reference formulation, respectively. Also, $\sigma_{B_T}^2$ and $\sigma_{B_R}^2$ are the intersubject variances for test and reference formulation, respectively.

Test for Equality

In practice, it is often of interest to test whether two drug products have the same intrasubject variability. The following hypotheses are then of interest:

$$H_0: \frac{\sigma_{w_T}^2}{\sigma_{w_R}^2} = 1 \quad \text{vs.} \quad H_a: \frac{\sigma_{w_T}^2}{\sigma_{w_R}^2} \neq 1 \quad (4)$$

A commonly used test statistic for testing the above hypotheses is given by

$$T = \frac{\hat{\sigma}_{w_T}^2}{\hat{\sigma}_{w_R}^2}$$

Under the null hypothesis, T is distributed as an F distribution with $n_T(m-1)$ and $n_R(m-1)$ degrees of freedom. Hence, we reject the null hypothesis at the α level of significance if

$$T > F_{\alpha/2, n_T(m-1), n_R(m-1)}$$

or

$$T < F_{1-\alpha/2, n_T(m-1), n_R(m-1)}$$

where $F_{\alpha/2, n_T(m-1), n_R(m-1)}$ is the upper $(\alpha/2) \times 100\%$ quantile of an F distribution with $n_T(m-1)$ and $n_R(m-1)$ degrees of freedom.

Test for Noninferiority/Superiority

The problem of testing noninferiority and superiority can be unified by the following hypotheses

$$H_0: \frac{\sigma_{w_T}^2}{\sigma_{w_R}^2} \geq \delta \quad \text{vs.} \quad H_a: \frac{\sigma_{w_T}^2}{\sigma_{w_R}^2} < \delta \quad (5)$$

When $\delta < 1$, the rejection of the null hypothesis indicates the superiority of the test product over the reference in terms of the intrasubject variability. When $\delta > 1$, the rejection of the null hypothesis indicates the noninferiority of the test product over the reference. The test statistic is given by

$$T = \frac{\hat{\sigma}_{w_T}^2}{\delta \hat{\sigma}_{w_R}^2}$$

Under the null hypothesis, T is distributed as an F random variable with $n_T(m-1)$ and $n_R(m-1)$ degrees of freedom. Hence, we reject the null hypothesis at the α level of significance if

$$T < F_{1-\alpha, n_T(m-1), n_R(m-1)}$$

Test for Similarity

For testing similarity, the following hypotheses are usually considered:

$$H_0: \frac{\sigma_{w_T}^2}{\sigma_{w_R}^2} \notin \left(\frac{1}{\delta}, \delta \right) \quad \text{vs.} \quad H_a: \frac{\sigma_{w_T}^2}{\sigma_{w_R}^2} \in \left(\frac{1}{\delta}, \delta \right) \quad (6)$$

where $\delta > 1$ is the similarity limit. The above hypotheses can be decomposed into the following two one-sided hypotheses:

$$\begin{aligned} H_{01}: \frac{\sigma_{w_T}^2}{\sigma_{w_R}^2} \geq \delta \quad \text{vs.} \quad H_{a1}: \frac{\sigma_{w_T}^2}{\sigma_{w_R}^2} < \delta \\ H_{02}: \frac{\sigma_{w_T}^2}{\sigma_{w_R}^2} \leq \frac{1}{\delta} \quad \text{vs.} \quad H_{a2}: \frac{\sigma_{w_T}^2}{\sigma_{w_R}^2} > \frac{1}{\delta} \end{aligned} \quad (7)$$

These two one-sided hypotheses can be tested by the following two test statistics

$$T_1 = \frac{\hat{\sigma}_{WT}^2}{\hat{\sigma}_{WR}^2} \quad \text{and} \quad T_2 = \frac{\delta \hat{\sigma}_{WT}^2}{\hat{\sigma}_{WR}^2}$$

We then reject the null hypothesis and conclude similarity at the α level of significance if

$$T_1 < F_{1-\alpha, n_T(m-1), n_R(m-1)} \quad \text{and} \quad T_2 > F_{\alpha, n_T(m-1), n_R(m-1)}$$

Replicated Crossover Design

Compared with the parallel design with replicates, the merit of a crossover design is the ability to make comparisons of treatment effect within subjects. In this section, without loss of generality, consider a $2 \times 2m$ replicated crossover design comparing two treatments. Under a $2 \times 2m$ replicated crossover design, in each sequence, each subject receives the test formulations m times and the reference formulations m times at different dosing periods. When $m = 1$, the $2 \times 2m$ replicated crossover design reduces to the standard two-sequence, two-period (2×2) crossover design. On the other hand, when $m = 2$, the $2 \times 2m$ replicated crossover design becomes a 2×4 crossover design, which is recommended by the United States Food and Drug Administration (FDA) for assessment of population/individual bioequivalence.^[10]

Suppose that n_1 subjects are assigned to the first sequence and n_2 subjects are assigned to the second sequence. Let x_{ijkl} be the observation from the j th subject ($j = 1, \dots, n_i$) in the i th sequence ($i = 1, 2$) under the l th replicate ($l = 1, \dots, m$) of the k th treatment ($k = T, R$). As indicated in Ref. [1], the following linear mixed effects model can be considered to describe a $2 \times 2m$ replicated crossover design:

$$x_{ijkl} = \mu_k + \gamma_{ikl} + S_{ijk} + \epsilon_{ijkl} \quad (8)$$

where μ_k is the treatment effect for formulation k , γ_{ikl} is the fixed effect of the l th replicate on treatment k in the i th sequence with constraint

$$\sum_{i=1}^2 \sum_{l=1}^m \gamma_{ikl} = 0$$

$(S_{ijT}, S_{ijR})'$ are the random effects of the j th subject in the i th sequence, which are independent and identically distributed as a bivariate normal random vector with mean $(0, 0)'$ and covariance matrix

$$\Sigma_B = \begin{pmatrix} \sigma_{BT}^2 & \rho \sigma_{BT} \sigma_{BR} \\ \rho \sigma_{BT} \sigma_{BR} & \sigma_{BR}^2 \end{pmatrix}$$

Note that σ_{BT}^2 and σ_{BR}^2 are intersubject variances under the test formulation and the reference formulation, respectively.

ϵ_{ijkl} s are independent random variables from the normal distribution with mean 0 and variance σ_{WT}^2 or σ_{WR}^2 , which are intrasubject variabilities under the test formulation and the reference formulation, respectively. It is assumed that $(S_{ijT}, S_{ijR})'$ and ϵ_{ijkl} are independent.

To obtain estimators of intrasubject variances, it is a common practice to use an orthogonal transformation, which is considered by Chinchilli and Esinhart.^[1] A new random variable z_{ijkl} can be obtained by using the orthogonal transformation

$$\mathbf{z}_{ijk} = \mathbf{P}' \mathbf{x}_{ijk} \quad (9)$$

where

$$\mathbf{x}'_{ijk} = (x_{ijk1}, x_{ijk2}, \dots, x_{ijkn})', \quad \mathbf{z}'_{ijk} = (z_{ijk1}, z_{ijk2}, \dots, z_{ijkn})'$$

and $\mathbf{P}$ is an $m \times m$ orthogonal transformation under which $\mathbf{P}'\mathbf{P}$ is an $m \times m$ diagonal matrix. The first column of $\mathbf{P}$ is usually defined by the vector $1/m(1, 1, \dots, 1)'$ to obtain $z_{ijk1} = \bar{x}_{ijk}$ and the other columns can be defined to satisfy the orthogonality of $\mathbf{P}$ and $\text{Var}(z_{ijkl}) = \sigma_{Wi}^2$ for $l = 2, \dots, m$. For example, in the 2×4 crossover design, the new random variable z_{ijkl} can be defined as

$$z_{ijk1} = \frac{x_{ijk1} + x_{ijk2}}{2} \equiv \bar{x}_{ijk}, \quad \text{and} \quad z_{ijk2} = \frac{x_{ijk1} - x_{ijk2}}{\sqrt{2}}$$

Now, the estimator of intrasubject variance can be defined as

$$\begin{aligned} \hat{\sigma}_{WT}^2 &= \frac{1}{(n_1 + n_2 - 2)(m - 1)} \sum_{i=1}^2 \sum_{j=1}^{n_i} \sum_{l=2}^m (z_{ijTl} - \bar{z}_{i.Tl})^2 \\ \hat{\sigma}_{WR}^2 &= \frac{1}{(n_1 + n_2 - 2)(m - 1)} \sum_{i=1}^2 \sum_{j=1}^{n_i} \sum_{l=2}^m (z_{ijRl} - \bar{z}_{i.Rl})^2 \end{aligned} \quad (10)$$

where

$$\bar{z}_{i.kl} = \frac{1}{n_i} \sum_{j=1}^{n_i} z_{ijkl}$$

It should be noted that $\hat{\sigma}_{WT}^2$ and $\hat{\sigma}_{WR}^2$ are independent and unbiased estimators for σ_{WT}^2 and σ_{WR}^2 , respectively.

Test for Equality

Under the null hypothesis of Eq. 4, a test statistic

$$T = \frac{\hat{\sigma}_{WT}^2}{\hat{\sigma}_{WR}^2}$$

is distributed as an F random variable with d and d degrees of freedom, where $d = (n_1 + n_2 - 2)(m - 1)$. Hence, we reject the null hypothesis at the α level of significance if

$$T > F_{\alpha/2, d, d} \quad \text{or} \quad T < F_{1-\alpha/2, d, d}$$

Test for Noninferiority/Superiority

Under the null hypothesis of Eq. 5, $T = \hat{\sigma}_{WT}^2 / \delta \hat{\sigma}_{WT}^2$ is distributed as an F random variable with d and d degrees of freedom. Hence, we reject the null hypothesis at the α level of significance if

$$T < F_{1-\alpha, d, d}$$

Test for Similarity

Under the two one-sided hypotheses as discussed in Eq. 7, the following two test statistics

$$T_1 = \frac{\hat{\sigma}_{WT}^2}{\delta \hat{\sigma}_{WR}^2} \quad \text{and} \quad T_2 = \frac{\delta \hat{\sigma}_{WT}^2}{\hat{\sigma}_{WR}^2}$$

are used. We then reject the null hypothesis and conclude similarity at the α level of significance if

$$T_1 < F_{1-\alpha, d, d} \quad \text{and} \quad T_2 > F_{\alpha, d, d}$$

COMPARING INTRASUBJECT COEFFICIENTS OF VARIATION

In addition to comparing intrasubject variabilities, it is often of interest to compare intrasubject CV, which is a relative standard deviation adjusted by the mean. In recent years, the use of intrasubject CV has become increasingly popular. For example, the FDA defines highly variable drug products based on their intrasubject CVs. A drug product is said to be a highly variable drug if its intrasubject CV is greater than 30%. The intrasubject CV is also used as a measure for reproducibility of blood levels (or blood concentration–time curves) of a given formulation when the formulation is repeatedly administered at different dosing periods. In addition, the information regarding the intrasubject CV of a reference product is usually used for performing power analysis for sample size calculation in bioavailability and bioequivalence studies. In practice, two methods are commonly used for comparing intrasubject CVs. One is proposed by Chow and Tse,^[8] which is referred to as conditional random effects model. The other one is suggested by Quan and Shih,^[9] which is a simple one-way random effects model. In what follows, we will briefly introduce these two methods.

Simple Random Effects Model

Quan and Shih^[9] developed a method to estimate the intrasubject CV based on the simple mixed effects model Eq. 1 under which the intrasubject variability is a constant for all subjects in the same treatment. An intuitive unbiased estimator for μ_i is then given by

$$\hat{\mu}_i = \frac{1}{n_i m} \sum_{j=1}^{n_i} \sum_{k=1}^m x_{ijk}$$

Hence, an estimator of the intrasubject CV can be obtained by, for $i = T, R$,

$$\widehat{CV}_i = \frac{\hat{\sigma}_{Wi}}{\hat{\mu}_i}$$

By Taylor's expansion, it follows that

$$\begin{aligned} \widehat{CV}_i - CV_i &= \frac{\hat{\sigma}_{Wi}}{\hat{\mu}_i} - \frac{\sigma_{Wi}}{\mu_i} \\ &\approx \frac{1}{2\mu_i\sigma_{Wi}}(\hat{\sigma}_{Wi}^2 - \sigma_{Wi}^2) - \frac{\sigma_{Wi}}{\mu_i^2}(\hat{\mu}_i - \mu_i) \end{aligned}$$

Hence, by central limit theorem (CLT), $\widehat{CV}_i$ is asymptotically distributed as a normal random variable with mean CV_i and variance σ_i^{*2}/n_i , where

$$\begin{aligned} \sigma_i^{*2} &= \frac{\sigma_{Wi}^2}{2m\mu_i^2} + \frac{\sigma_{Wi}^4}{\mu_i^4} \\ &= \frac{1}{2m}CV_i^2 + CV_i^4 \end{aligned}$$

Thus, an intuitive estimator of σ_i^{*2} is given by

$$\hat{\sigma}_i^{*2} = \frac{1}{2m}\widehat{CV}_i^2 + \widehat{CV}_i^4$$

Test for Equality

The following hypotheses are usually considered for testing equality in intrasubject CVs

$$H_0: CV_T = CV_R \quad \text{vs.} \quad H_a: CV_T \neq CV_R \quad (11)$$

Under the null hypothesis, the test statistic

$$T = \frac{\widehat{CV}_T - \widehat{CV}_R}{\sqrt{\hat{\sigma}_T^{*2}/n_T + \hat{\sigma}_R^{*2}/n_R}}$$

is asymptotically distributed as a standard normal random variable. Hence, we reject the null hypothesis at the α level of significance if $|T| > z_{\alpha/2}$.

Test for Noninferiority/Superiority

Similarly, the problem of testing noninferiority and superiority can be unified by the following hypotheses:

$$H_0: CV_T - CV_R \geq \delta \quad \text{vs.} \quad H_a: CV_T - CV_R < \delta \quad (12)$$

where δ is the noninferiority/superiority margin. When $\delta > 0$, the rejection of the null hypothesis indicates the noninferiority of the test formulation over the reference formulation. When $\delta < 0$, the rejection of the null hypothesis indicates the superiority of the test formulation over the reference formulation.

Under the null hypothesis, the test statistic

$$T = \frac{\widehat{CV}_T - \widehat{CV}_R - \delta}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}}$$

is asymptotically distributed as a standard normal random variable. Hence, we reject the null hypothesis at the α level of significance if $T < -z_\alpha$.

Test for Similarity

For testing similarity, the following hypotheses are usually considered:

$$H_0: |\widehat{CV}_T - \widehat{CV}_R| \geq \delta \quad \text{vs.} \quad H_a: |\widehat{CV}_T - \widehat{CV}_R| < \delta \quad (13)$$

The two drug products are concluded similar to each other if the null hypothesis is rejected at a given significance level. The null hypothesis is rejected at the α level of significance if

$$\frac{\widehat{CV}_T - \widehat{CV}_R + \delta}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}} > z_\alpha \quad \text{and} \quad \frac{\widehat{CV}_T - \widehat{CV}_R - \delta}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}} < -z_\alpha$$

Conditional Random Effects Model

In practice, the variability of the observed response often increases as the mean increases. In many cases, the standard deviation of the intrasubject variability is approximately proportional to the mean value. To best describe this type of data, Chow and Tse^[8] proposed the following conditional random effects model.

$$x_{ijk} = A_{ij} + A_{ij} e_{ijk} \quad (14)$$

where x_{ijk} is the observation from the k th replicate ($k = 1, \dots, m$) of the j th subject ($j = 1, \dots, n_i$) from the i th treatment ($i = T, R$) and A_{ij} is the random effect due to the j th subject in the i th treatment. It is assumed that A_{ij} is normally distributed as a normal random variable with mean μ_i and variance σ_{Bi}^2 and e_{ijk} is normally distributed as a normal random variable with mean 0 and variance σ_{wi}^2 . For a given subject with a fixed A_{ij} , x_{ijk} is normally distributed as a normal random variable with mean A_{ij} and variance $A_{ij}^2 \sigma_{wi}^2$. Hence, the CV for this subject is given by

$$CV = \frac{|A_{ij} \sigma_{wi}|}{|A_{ij}|} = \sigma_{wi}$$

As can be seen, the conditional random effects model assumes the CV is a constant across subjects.

Define

$$\begin{aligned} \bar{x}_{i..} &= \frac{1}{nm} \sum_{j=1}^{n_i} \sum_{k=1}^m x_{ijk} \\ M_{i1} &= \frac{m}{n_i - 1} \sum_{j=1}^{n_i} (\bar{x}_{ij.} - \bar{x}_{i..})^2 \\ M_{i2} &= \frac{1}{n_i(m_i - 1)} \sum_{j=1}^{n_i} \sum_{k=1}^m (x_{ijk} - \bar{x}_{ij.})^2 \end{aligned}$$

It can be verified that

$$\begin{aligned} E(\bar{x}_{i..}) &= \mu_i \\ E(M_{i1}) &= (\mu_i^2 + \sigma_{BT}^2) \sigma_{wi}^2 + m \sigma_{Bi}^2 = \tau_{i1}^2 \\ E(M_{i2}) &= (\mu_i^2 + \sigma_{BT}^2) \sigma_{wi}^2 = \tau_{i2}^2 \end{aligned}$$

It follows that

$$CV_i = \sigma_{wi} = \sqrt{\frac{E(M_{i2})}{E^2(\bar{x}_{i..}) + (M_{i1} - M_{i2})}}$$

Hence, an estimator for CV_i is given by

$$\widehat{CV}_i = \sqrt{\frac{M_{i2}}{\bar{x}_{i..}^2 + (M_{i1} - M_{i2})/m}}$$

By Taylor's expansion,

$$\begin{aligned} \widehat{CV}_i - CV_i &\approx \frac{1}{\tau_{i1} \tau_{i2}} (M_{i2} - \tau_{i2}^2) \\ &\quad - \frac{\mu_i \tau_{i2}}{\tau_{i1}^3} (\bar{x}_{i..} - \mu_i) - \frac{\tau_{i2}}{2m \tau_{i1}^3} (M_{i1} - M_{i2} - (\tau_{i1}^2 - \tau_{i2}^2)) \\ &= k_0 (\bar{x}_{i..} - \mu_i) + k_1 (M_{i1} - \tau_{i1}^2) + k_2 (M_{i2} - \tau_{i2}^2) \end{aligned}$$

where

$$\begin{aligned} k_0 &= -\frac{\mu_i \tau_{i2}}{\tau_{i1}^3} \\ k_1 &= -\frac{\tau_{i2}}{2m \tau_{i1}^3} \\ k_2 &= \left(\frac{1}{\tau_{i1} \tau_{i2}} + \frac{\tau_{i2}}{2m \tau_{i1}^3} \right) \end{aligned}$$

As a result, $\widehat{CV}_i$'s distribution can be approximated by a normal random variable with mean CV_i and variance σ_i^{*2}/n_i where

$$\sigma_i^{*2} = \text{var} \left[k_0 \bar{x}_{ij.} + m k_1 (\bar{x}_{ij.} - \bar{x}_{i..})^2 + \frac{k_2}{m-1} \sum_{k=1}^m (x_{ijk} - \bar{x}_{ij.})^2 \right]$$

An intuitive estimator for σ_i^{*2} is the sample variance, denoted by $\hat{\sigma}_i^{*2}$, of

$$\begin{aligned} k_0 \bar{x}_{ij.} + m k_1 (\bar{x}_{ij.} - \bar{x}_{i..})^2 + \frac{k_2}{m-1} \sum_{k=1}^m (x_{ijk} - \bar{x}_{ij.})^2 \\ j = 1, \dots, n_i \end{aligned}$$

Test for Equality

Under the null hypothesis in Eq. 11, the test statistic

$$T = \frac{\widehat{CV}_T - \widehat{CV}_R}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}}$$

is asymptotically distributed as a standard normal random variable. Hence, we reject the null hypothesis at the α level of significance if $|T| > z_{\alpha/2}$.

Test for Noninferiority/Superiority

Under the null hypothesis of Eq. 12, the test statistic

$$T = \frac{\widehat{CV}_T - \widehat{CV}_R - \delta}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}}$$

is asymptotically distributed as a standard normal random variable. Hence, we reject the null hypothesis at the α level of significance if $T < -z_\alpha$.

Test for Similarity

For testing similarity, consider the hypotheses

$$H_0: |\widehat{CV}_T - \widehat{CV}_R| \geq \delta \quad \text{vs.} \quad H_a: |\widehat{CV}_T - \widehat{CV}_R| < \delta$$

The two drug products are concluded similar to each other if the null hypothesis is rejected at a given significance level. The null hypothesis is rejected at α level of significance if

$$\begin{aligned} \frac{\widehat{CV}_T - \widehat{CV}_R + \delta}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}} &> z_\alpha \quad \text{vs.} \\ \frac{\widehat{CV}_T - \widehat{CV}_R - \delta}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}} &< -z_\alpha \end{aligned}$$

COMPARING INTERSUBJECT VARIABILITIES

In addition to comparing intrasubject variabilities or intrasubject CVs, it is also of interest to compare intersubject variabilities. In practice, it is not uncommon that clinical results may not be reproducible from subject to subject within the target population or from subjects within the target population to subjects within a similar but slightly different population due to the intersubject variability. How to test a difference in intersubject and total variability between two treatments is a challenging problem to clinical scientists, especially biostatisticians, because of the following reasons. First, unbiased estimators of the intersubject and total variabilities are

usually not chi-square distributed under both parallel and crossover design with replicates. Second, the estimators for the intersubject and total variabilities under different treatments are usually not independent under a crossover design. As a result, unlike tests for comparing intrasubject variabilities, the standard F -test is not applicable. Tests for comparing intersubject variabilities under a parallel design can be performed by using the MLS method (see Refs. [2–5]). As indicated earlier, the MLS method is superior to many other approximation methods. Under crossover designs, however, the MLS method cannot be directly applied because estimators of variance components are not independent. Lee et al.^[6] proposed an extension of the MLS method when estimators of variance components are not independent. In addition, tests for comparing intersubject and total variabilities under crossover designs are studied by Lee et al.^[7] Note that the MLS method by Hyslop et al.^[5] is recommended as a statistical test for individual bioequivalence by the FDA.^[10]

Parallel Design with Replicates

Under model Eq. 1, for $i = T, R$, define

$$s_{Bi}^2 = \frac{1}{n_i - 1} \sum_{j=1}^{n_i} (\bar{x}_{ij} - \bar{x}_{i..})^2 \quad (15)$$

where $\bar{x}_{ij}$ is given in Eq. 3 and

$$\bar{x}_{i..} = \frac{1}{n_i} \sum_{j=1}^{n_i} \bar{x}_{ij}$$

Note that $E(s_{Bi}^2) = \sigma_{Bi}^2 + \sigma_{wi}^2/m$. Therefore, the unbiased estimators for the intersubject variances are given by

$$\hat{\sigma}_{Bi}^2 = s_{Bi}^2 - \frac{1}{m} \hat{\sigma}_{wi}^2$$

where $\hat{\sigma}_{wi}^2$ is defined in Eq. 2.

Test for Equality

For testing equality in intersubject variability, the following hypotheses are usually considered

$$H_0: \frac{\sigma_{BT}^2}{\sigma_{BR}^2} = 1 \quad \text{vs.} \quad H_a: \frac{\sigma_{BT}^2}{\sigma_{BR}^2} \neq 1 \quad (16)$$

Testing the above hypotheses is equivalent to testing the following hypotheses

$$H_0: \sigma_{BT}^2 - \sigma_{BR}^2 = 0 \quad \text{vs.} \quad H_a: \sigma_{BT}^2 - \sigma_{BR}^2 \neq 0 \quad (17)$$

Let $\eta = \sigma_{BT}^2 - \sigma_{BR}^2$. An intuitive estimator of η is given by

$$\hat{\eta} = \hat{\sigma}_{BT}^2 - \hat{\sigma}_{BR}^2$$

It follows that

$$\begin{aligned}\hat{\eta} &= \hat{\sigma}_{BR}^2 - \hat{\sigma}_{BT}^2 \\ &= s_{BT}^2 - s_{BR}^2 - \hat{\sigma}_{WT}^2/m + \hat{\sigma}_{WR}^2/m\end{aligned}$$

A $(1 - \alpha) \times 100\%$ MLS confidence interval of η is given by

$$(\hat{\eta}_L, \hat{\eta}_U)$$

where

$$\hat{\eta}_L = \hat{\eta} - \sqrt{\Delta_L}, \quad \hat{\eta}_U = \hat{\eta} + \sqrt{\Delta_U}$$

and

$$\begin{aligned}\Delta_L &= s_{BT}^4 \left(1 - \frac{n_T - 1}{\chi_{\alpha/2, n_T - 1}^2}\right)^2 + s_{BR}^4 \left(1 - \frac{n_R - 1}{\chi_{1-\alpha/2, n_R - 1}^2}\right)^2 \\ &\quad + \frac{\hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_T(m-1)}{\chi_{1-\alpha/2, n_T(m-1)}^2}\right)^2 + \frac{\hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_R(m-1)}{\chi_{\alpha/2, n_R(m-1)}^2}\right)^2 \\ \Delta_U &= s_{BT}^4 \left(1 - \frac{n_T - 1}{\chi_{1-\alpha/2, n_T - 1}^2}\right)^2 + s_{BR}^4 \left(1 - \frac{n_R - 1}{\chi_{\alpha/2, n_R - 1}^2}\right)^2 \\ &\quad + \frac{\hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_T(m-1)}{\chi_{\alpha/2, n_T(m-1)}^2}\right)^2 + \frac{\hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_R(m-1)}{\chi_{1-\alpha/2, n_R(m-1)}^2}\right)^2\end{aligned}$$

We reject the null hypothesis at the α level of significance if $0 \notin (\hat{\eta}_L, \hat{\eta}_U)$.

Test for Noninferiority/Superiority

Similar to testing intrasubject variabilities, the problem of testing noninferiority/superiority can be unified by the following hypotheses

$$H_0: \frac{\sigma_{BT}^2}{\sigma_{BR}^2} \geq \delta \quad \text{vs.} \quad H_a: \frac{\sigma_{BT}^2}{\sigma_{BR}^2} < \delta \quad (18)$$

Testing the above hypotheses is equivalent to testing the following hypotheses

$$H_0: \sigma_{BT}^2 - \delta\sigma_{BR}^2 \geq 0 \quad \text{vs.} \quad H_1: \sigma_{BT}^2 - \delta\sigma_{BR}^2 < 0 \quad (19)$$

Define

$$\eta = \sigma_{BT}^2 - \delta\sigma_{BR}^2$$

For a given significance level α , similarly, the $(1 - \alpha) \times 100\%$ th MLS upper confidence bound of η can be constructed as

$$\hat{\eta}_U = \hat{\eta} + \sqrt{\Delta_U}$$

where Δ_U is given by

$$\begin{aligned}\Delta_U &= s_{BT}^4 \left(1 - \frac{n_T - 1}{\chi_{1-\alpha, n_T - 1}^2}\right)^2 + \delta^2 s_{BR}^4 \left(1 - \frac{n_R - 1}{\chi_{\alpha, n_R - 1}^2}\right)^2 \\ &\quad + \frac{\hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_T(m-1)}{\chi_{\alpha, n_T(m-1)}^2}\right)^2 \\ &\quad + \frac{\delta^2 \hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_R(m-1)}{\chi_{1-\alpha, n_R(m-1)}^2}\right)^2\end{aligned}$$

We then reject the null hypothesis at the α level of significance if $\hat{\eta}_U < 0$.

Test for Similarity

Similarly, consider the following hypotheses for establishment of similarity in variability:

$$H_0: \frac{\sigma_{BT}^2}{\sigma_{BR}^2} \notin \left(\frac{1}{\delta}, \delta\right) \quad \text{vs.} \quad H_a: \frac{\sigma_{BT}^2}{\sigma_{BR}^2} \in \left(\frac{1}{\delta}, \delta\right) \quad (20)$$

where $\delta > 1$ is the similarity limit. The above hypotheses can be decomposed into the following two one-sided hypotheses:

$$\begin{aligned}H_{01}: \sigma_{BT}^2 - \delta\sigma_{BR}^2 \geq 0 \quad \text{vs.} \quad H_{a1}: \sigma_{BT}^2 - \delta\sigma_{BR}^2 < 0 \\ H_{02}: \delta\sigma_{BT}^2 - \sigma_{BR}^2 \leq 0 \quad \text{vs.} \quad H_{a2}: \delta\sigma_{BT}^2 - \sigma_{BR}^2 > 0\end{aligned} \quad (21)$$

Similarity in intersubject variability between two treatments can be established if both of the above two hypotheses are rejected at the α level of significance. The test can be performed by constructing the $(1 - \alpha) \times 100\%$ upper confidence bound of $\eta_1 = \sigma_{BT}^2 - \delta\sigma_{BR}^2$ and the $(1 - \alpha) \times 100\%$ lower confidence bound of $\eta_2 = \delta\sigma_{BT}^2 - \sigma_{BR}^2$ by the MLS method. For example, the $(1 - \alpha) \times 100\%$ lower confidence bound of η_2 is given by

$$\hat{\eta}_{2L} = \hat{\eta}_2 - \sqrt{\Delta_L}$$

where

$$\begin{aligned}\Delta_L &= \delta^2 s_{BT}^4 \left(1 - \frac{n_T - 1}{\chi_{\alpha, n_T - 1}^2}\right)^2 + s_{BR}^4 \left(1 - \frac{n_R - 1}{\chi_{1-\alpha, n_R - 1}^2}\right)^2 \\ &\quad + \frac{\delta^2 \hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_T(m-1)}{\chi_{1-\alpha, n_T(m-1)}^2}\right)^2 + \frac{\hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_R(m-1)}{\chi_{\alpha, n_R(m-1)}^2}\right)^2\end{aligned}$$

Replicated Crossover Design

Under model Eq. 8 and new random variable $z_{ijk1} \equiv \bar{x}_{ijk}$ in Eq. 9, the intersubject sums of squares are defined by

$$\begin{aligned} s_{BT}^2 &= \frac{1}{n_1 + n_2 - 2} \sum_{i=1}^2 \sum_{j=1}^{n_i} (\bar{x}_{ijT} - \bar{x}_{i.T})^2 \\ s_{BR}^2 &= \frac{1}{n_1 + n_2 - 2} \sum_{i=1}^2 \sum_{j=1}^{n_i} (\bar{x}_{ijR} - \bar{x}_{i.R})^2 \end{aligned} \quad (22)$$

where

$$\bar{x}_{i.k.} = \frac{1}{n_i} \sum_{j=1}^{n_i} \bar{x}_{ijk}.$$

Note that $E(s_{Bk}^2) = \sigma_{Bk}^2 + \sigma_{wk}^2/m$ for $k = T, R$. Therefore, the unbiased estimators for the intersubject variance are given by

$$\hat{\sigma}_{BT}^2 = s_{BT}^2 - \frac{1}{m} \hat{\sigma}_{WT}^2 \quad (23)$$

$$\hat{\sigma}_{BR}^2 = s_{BR}^2 - \frac{1}{m} \hat{\sigma}_{WR}^2 \quad (24)$$

where $\hat{\sigma}_{WT}^2$ and $\hat{\sigma}_{WR}^2$ are defined in Eq. 10.

Test for Equality

For testing the equality in intersubject variability, the hypotheses in Eq. 17 are considered. Let $\eta = \sigma_{BT}^2 - \sigma_{BR}^2$. An intuitive estimator of η is given by

$$\hat{\eta} = \hat{\sigma}_{BT}^2 - \hat{\sigma}_{BR}^2$$

where $\hat{\sigma}_{BT}^2$ and $\hat{\sigma}_{BR}^2$ are given in Eqs. 23 and 24, respectively. It follows that

$$\begin{aligned} \hat{\eta} &= \hat{\sigma}_{BT}^2 - \hat{\sigma}_{BR}^2 \\ &= s_{BT}^2 - s_{BR}^2 - \frac{1}{m} \hat{\sigma}_{WT}^2 + \frac{1}{m} \hat{\sigma}_{WR}^2 \end{aligned}$$

Mean vector for the j th subject in i th sequence $(\bar{x}_{ijT}, \bar{x}_{ijR})'$ has a bivariate normal distribution with covariance matrix given by

$$\Omega_B = \begin{pmatrix} \sigma_{BT}^2 + \sigma_{WT}^2/m & \rho \sigma_{BT} \sigma_{BR} \\ \rho \sigma_{BT} \sigma_{BR} & \sigma_{BR}^2 + \sigma_{WR}^2/m \end{pmatrix} \quad (25)$$

The unbiased estimator of covariance matrix Ω_B can be obtained as

$$\hat{\Omega}_B = \begin{pmatrix} s_{BT}^2 & s_{BTR}^2 \\ s_{BTR}^2 & s_{BR}^2 \end{pmatrix} \quad (26)$$

where

$$s_{BTR}^2 = \frac{1}{n_1 + n_2 - 2} \sum_{i=1}^2 \sum_{j=1}^{n_i} (\bar{x}_{ijT} - \bar{x}_{i.T})(\bar{x}_{ijR} - \bar{x}_{i.R})$$

which is the sample covariance between $\bar{x}_{ijT}$ and $\bar{x}_{ijR}$. Let $\lambda_i, i = 1, 2$ be the two eigenvalues of the matrix $\Theta \hat{\Omega}_B$ where

$$\Theta = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \quad (27)$$

Hence, the population eigenvalues $\lambda_i, i = 1, 2$ can be estimated by the sample eigenvalues of $\Theta \hat{\Omega}_B$ and the explicit form of estimators is given as

$$\hat{\lambda}_i = \frac{s_{BT}^2 - s_{BR}^2 \pm \sqrt{(s_{BT}^2 + s_{BR}^2) - 4s_{BTR}^2}}{2} \quad \text{for } i = 1, 2$$

Without loss of generality, it can be assumed that $\hat{\lambda}_1$. By the extension of the MLS method in Ref. [7], a $(1 - \alpha) \times 100\%$ MLS confidence interval of η is given by

$$(\hat{\eta}_L, \hat{\eta}_U)$$

where

$$\hat{\eta}_L = \hat{\eta} - \sqrt{\Delta_L}, \quad \hat{\eta}_U = \hat{\eta} + \sqrt{\Delta_U}$$

and

$$\begin{aligned} \Delta_L &= \hat{\lambda}_1^2 \left(1 - \frac{n_s - 1}{\chi_{\alpha/2, n_s - 1}^2} \right)^2 + \hat{\lambda}_2^2 \left(1 - \frac{n_s - 1}{\chi_{1-\alpha/2, n_s - 1}^2} \right)^2 \\ &\quad + \frac{\hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{\alpha/2, n_s(m-1)}^2} \right)^2 + \frac{\hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{1-\alpha/2, n_s(m-1)}^2} \right)^2 \\ \Delta_U &= \hat{\lambda}_1^2 \left(1 - \frac{n_s - 1}{\chi_{1-\alpha/2, n_s - 1}^2} \right)^2 + \hat{\lambda}_2^2 \left(1 - \frac{n_s - 1}{\chi_{\alpha/2, n_s - 1}^2} \right)^2 \\ &\quad + \frac{\hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{1-\alpha/2, n_s(m-1)}^2} \right)^2 + \frac{\hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{\alpha/2, n_s(m-1)}^2} \right)^2 \end{aligned}$$

where $n_s = n_1 + n_2 - 2$. Then, we reject the null hypothesis at the α level of significance if $0 \notin (\hat{\eta}_L, \hat{\eta}_U)$.

Test for Noninferiority/Superiority

Similar to testing intrasubject variabilities, the problem of testing noninferiority/superiority can be unified by the hypotheses described in Eq. 19. For a given significance level of α , the $(1 - \alpha) \times 100\%$ MLS upper confidence bound of $\eta = \sigma_{BT}^2 - \delta \sigma_{BR}^2$ can be constructed as

$$\hat{\eta}_U = \hat{\eta} + \sqrt{\Delta_U}$$

where Δ_U is given by

$$\Delta_U = \hat{\lambda}_1^2 \left(1 - \frac{n_s - 1}{\chi_{1-\alpha, n_s-1}^2} \right)^2 + \hat{\lambda}_2^2 \left(1 - \frac{n_s - 1}{\chi_{\alpha, n_s-1}^2} \right)^2 + \frac{\hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{1-\alpha, n_s(m-1)}^2} \right)^2 + \frac{\delta^2 \hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{\alpha, n_s(m-1)}^2} \right)^2$$

where $n_s = n_1 + n_2 - 2$ and $\hat{\lambda}_1 < 0 < \hat{\lambda}_2$ are the eigenvalues of $\Theta \hat{\Omega}_B$ with

$$\Theta = \begin{pmatrix} 1 & 0 \\ 0 & -\delta \end{pmatrix} \quad (28)$$

Test for Similarity

Consider the hypotheses in Eq. 21 for establishment of similarity in intersubject variability. Similarity between two treatments can be established if both of the two hypotheses in Eq. 21 are rejected at the α level of significance. The test can be performed by constructing the $(1 - \alpha) \times 100\%$ upper confidence bound of $\eta_1 = \sigma_{BT}^2 - \delta \sigma_{BR}^2$ and the $(1 - \alpha) \times 100\%$ lower confidence bound of $\eta_2 = \delta \sigma_{BT}^2 - \sigma_{BR}^2$ by the MLS method. For example, the $(1 - \alpha) \times 100\%$ lower confidence bound of η_2 is given by

$$\hat{\eta}_{2L} = \hat{\eta}_2 - \sqrt{\Delta_L}$$

where

$$\Delta_L = \hat{\lambda}_1^2 \left(1 - \frac{n_s - 1}{\chi_{\alpha, n_s-1}^2} \right)^2 + \hat{\lambda}_2^2 \left(1 - \frac{n_s - 1}{\chi_{1-\alpha, n_s-1}^2} \right)^2 + \frac{\delta^2 \hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{\alpha, n_s(m-1)}^2} \right)^2 + \frac{\hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{1-\alpha, n_s(m-1)}^2} \right)^2$$

where $n_s = n_1 + n_2 - 2$ and $\hat{\lambda}_1 < 0 < \hat{\lambda}_2$ are the eigenvalues of $\Theta \hat{\Omega}_B$ with

$$\Theta = \begin{pmatrix} \delta & 0 \\ 0 & -1 \end{pmatrix} \quad (29)$$

COMPARING TOTAL VARIABILITIES

In practice, it may be also of interest to compare total variabilities between drug products. Total variability is related to the drug's prescribability,^[10] which is the main concept for population bioequivalence. Because the total variability can be estimated under parallel/crossover designs both with and without replicates, we will consider both designs with and without replicates.

Parallel Designs Without Replicates

The following model can be used for a parallel design without replicates

$$x_{ij} = \mu_i + \epsilon_{ij}$$

where x_{ij} is the observation from the j th subject in the i th treatment group. Also we assume that the random variable ϵ_{ij} has normal distribution with mean 0 and variance σ_{Ti}^2 for $i = T, R$. Hence, the total variability can be estimated by

$$\hat{\sigma}_{Ti}^2 = \frac{1}{n_i - 1} \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_{i.})^2$$

where

$$\bar{x}_{i.} = \frac{1}{n_i} \sum_{j=1}^{n_i} x_{ij}$$

Test for Equality

For testing equality in total variability, the following hypotheses are considered:

$$H_0: \frac{\sigma_{TT}^2}{\sigma_{TR}^2} = 1 \quad \text{vs.} \quad H_a: \frac{\sigma_{TT}^2}{\sigma_{TR}^2} \neq 1 \quad (30)$$

Under the null hypothesis, the test statistic

$$T = \frac{\hat{\sigma}_{TT}^2}{\hat{\sigma}_{TR}^2}$$

is distributed as an F random variable with $n_T - 1$ and $n_R - 1$ degrees of freedom. Hence, we reject the null hypothesis at the α level of significance if

$$T > F_{\alpha/2, n_T, n_R}$$

or

$$T < F_{1-\alpha/2, n_T, n_R}$$

Test for Noninferiority/Superiority

Similarly, the problem of testing noninferiority and superiority can be unified by the following hypotheses

$$H_0: \frac{\sigma_{TT}^2}{\sigma_{TR}^2} \geq \delta \quad \text{vs.} \quad H_a: \frac{\sigma_{TT}^2}{\sigma_{TR}^2} < \delta \quad (31)$$

The test statistic is given by

$$T = \frac{s_{TT}^2}{\delta s_{TR}^2}$$

Under the null hypothesis, T is distributed as an F random variable with $n_T - 1$ and $n_R - 1$ degrees of freedom. Hence, we reject the null hypothesis at the α level of significance if

$$T < F_{1-\alpha, n_R, n_T}$$

Test for Similarity

For testing similarity, the hypotheses of interest are given by

$$H_0: \frac{\sigma_{TT}^2}{\sigma_{TR}^2} \notin \left(\frac{1}{\delta}, \delta\right) \quad \text{vs.} \quad H_a: \frac{\sigma_{TT}^2}{\sigma_{TR}^2} \in \left(\frac{1}{\delta}, \delta\right) \quad (32)$$

where $\delta > 1$ is the similarity limit. The above hypotheses can be decomposed into the following two one-sided hypotheses

$$\begin{aligned} H_{01}: \frac{\sigma_{TT}^2}{\sigma_{TR}^2} \geq \delta \quad \text{vs.} \quad H_{a1}: \frac{\sigma_{TT}^2}{\sigma_{TR}^2} < \delta \\ H_{02}: \frac{\sigma_{TT}^2}{\sigma_{TR}^2} \leq \frac{1}{\delta} \quad \text{vs.} \quad H_{a2}: \frac{\sigma_{TT}^2}{\sigma_{TR}^2} > \frac{1}{\delta} \end{aligned} \quad (33)$$

These two hypotheses can be tested by the following two test statistics

$$T_1 = \frac{s_{TT}^2}{\delta s_{TR}^2} \quad \text{and} \quad T_2 = \frac{\delta s_{TT}^2}{s_{TR}^2}$$

We then reject the null hypothesis and conclude similarity at the α level of significance if

$$T_1 < F_{1-\alpha, n_T, n_R} \quad \text{and} \quad T_2 > F_{\alpha, n_T, n_R}$$

Parallel Design with Replicates

In practice, a parallel design with replicates can also be used to assess total variability. Although total variabilities can be assessed by the design without replicates, there is a merit of the design with replicates. Because intersubject and intrasubject variabilities can be assessed under a parallel design with replicates, it can serve more than just one purpose. If we consider model Eq. 1, an unbiased estimator for total variabilities is given by

$$\hat{\sigma}_{Ti}^2 = s_{Bi}^2 + \frac{m-1}{m} \hat{\sigma}_{wi}^2$$

where s_{Bi}^2 is defined in Eq. 15 and $\hat{\sigma}_{wi}^2$ is defined in Eq. (2). Let $\eta = \sigma_{TT}^2 - \sigma_{TR}^2$. Then, a natural estimator for η is given by

$$\hat{\eta} = \hat{\sigma}_{TT}^2 - \hat{\sigma}_{TR}^2$$

Test for Equality

For testing the equality in total variability, consider the hypotheses in Eq. 30, which is equivalent to testing the following hypotheses:

$$H_0: \sigma_{TT}^2 - \sigma_{TR}^2 = 0 \quad \text{vs.} \quad H_a: \sigma_{TT}^2 - \sigma_{TR}^2 \neq 0 \quad (34)$$

A $(1 - \alpha) \times 100\%$ MLS confidence interval of η is given by

$$(\hat{\eta}_L, \hat{\eta}_U)$$

where

$$\hat{\eta}_L = \hat{\eta} - \sqrt{\Delta_L}, \quad \hat{\eta}_U = \hat{\eta} + \sqrt{\Delta_U}$$

and

$$\begin{aligned} \Delta_L &= s_{BT}^4 \left(1 - \frac{n_T - 1}{\chi_{\alpha/2, n_T-1}^2}\right)^2 + s_{BR}^4 \left(1 - \frac{n_R - 1}{\chi_{1-\alpha/2, n_R-1}^2}\right)^2 \\ &\quad + \frac{(m-1)^2 \hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_T(m-1)}{\chi_{1-\alpha/2, n_T(m-1)}^2}\right)^2 \\ &\quad + \frac{(m-1)^2 \hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_R(m-1)}{\chi_{\alpha/2, n_R(m-1)}^2}\right)^2 \\ \Delta_U &= s_{BT}^4 \left(1 - \frac{n_T - 1}{\chi_{1-\alpha/2, n_T-1}^2}\right)^2 + s_{BR}^4 \left(1 - \frac{n_R - 1}{\chi_{\alpha/2, n_R-1}^2}\right)^2 \\ &\quad + \frac{(m-1)^2 \hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_T(m-1)}{\chi_{\alpha/2, n_T(m-1)}^2}\right)^2 \\ &\quad + \frac{(m-1)^2 \hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_R(m-1)}{\chi_{1-\alpha/2, n_R(m-1)}^2}\right)^2 \end{aligned}$$

We reject the null hypothesis at the α level of significance if $0 \notin (\hat{\eta}_L, \hat{\eta}_U)$.

Test for Noninferiority/Superiority

Similar to testing intrasubject variabilities, the problem of testing noninferiority/superiority can be unified by the hypotheses described in Eq. 31. Testing the hypotheses in Eq. 31 is equivalent to testing the following hypotheses:

$$H_0: \sigma_{TT}^2 - \delta \sigma_{TR}^2 \geq 0 \quad \text{vs.} \quad H_a: \sigma_{TT}^2 - \delta \sigma_{TR}^2 < 0 \quad (35)$$

Let $\eta = \sigma_{TT}^2 - \delta \sigma_{TR}^2$. For a given significance level of α , similarly, the $(1 - \alpha)100\%$ upper confidence bound of η can be constructed as

$$\hat{\eta}_U = \hat{\eta} + \sqrt{\Delta_U}$$

where $\hat{\eta} = \hat{\sigma}_{\text{TT}}^2 - \hat{\sigma}_{\text{TR}}^2$ and Δ_U is given by

$$\begin{aligned}\Delta_U = & s_{\text{BT}}^4 \left(1 - \frac{n_{\text{T}} - 1}{\chi_{1-\alpha, n_{\text{T}}-1}^2} \right)^2 + \delta^2 s_{\text{BR}}^4 \left(1 - \frac{n_{\text{R}} - 1}{\chi_{\alpha/2, n_{\text{R}}-1}^2} \right)^2 \\ & + \frac{(m-1)^2 \hat{\sigma}_{\text{WT}}^4}{m^2} \left(1 - \frac{n_{\text{T}}(m-1)}{\chi_{\alpha, n_{\text{T}}(m-1)}^2} \right)^2 \\ & + \frac{\delta^2 (m-1)^2 \hat{\sigma}_{\text{WR}}^4}{m^2} \left(1 - \frac{n_{\text{R}}(m-1)}{\chi_{1-\alpha, n_{\text{R}}(m-1)}^2} \right)^2\end{aligned}$$

We then reject the null hypothesis at the α level of significance if $\hat{\eta}_U < 0$.

Test for Similarity

For testing similarity, the hypotheses of interest are described in Eq. 33. We then reject the null hypothesis and conclude similarity at the α level of significance if both hypotheses in Eq. 33 are rejected with significance level α . The test can be performed by constructing the $(1 - \alpha) \times 100\%$ upper confidence bound of $\eta_1 = \sigma_{\text{TT}}^2 - \delta \sigma_{\text{TR}}^2$ and the $(1 - \alpha) \times 100\%$ lower confidence bound of $\eta_2 = \sigma_{\text{TT}}^2 - \delta \sigma_{\text{TR}}^2$ by the MLS method. For example, the $(1 - \alpha) \times 100\%$ lower confidence bound of η_2 is given by

$$\hat{\eta}_{2\text{L}} = \hat{\eta}_2 - \sqrt{\Delta_{\text{L}}}$$

Where

$$\begin{aligned}\Delta_{\text{L}} = & \delta^2 s_{\text{BT}}^4 \left(1 - \frac{n_{\text{T}} - 1}{\chi_{\alpha, n_{\text{T}}-1}^2} \right)^2 + s_{\text{BR}}^4 \left(1 - \frac{n_{\text{R}} - 1}{\chi_{1-\alpha, n_{\text{R}}-1}^2} \right)^2 \\ & + \frac{(m-1)^2 \delta^2 \hat{\sigma}_{\text{WT}}^4}{m^2} \left(1 - \frac{n_{\text{T}}(m-1)}{\chi_{1-\alpha, n_{\text{T}}(m-1)}^2} \right)^2 \\ & + \frac{(m-1)^2 \hat{\sigma}_{\text{WR}}^4}{m^2} \left(1 - \frac{n_{\text{R}}(m-1)}{\chi_{\alpha, n_{\text{R}}(m-1)}^2} \right)^2\end{aligned}$$

The Standard 2×2 Crossover Design

For the standard 2×2 crossover design, model Eq. 8 is still useful if the index for replicates l is omitted (i.e., $m = 1$). Unbiased estimators for the total variabilities are given by

$$\begin{aligned}\hat{\sigma}_{\text{TT}}^2 = s_{\text{BT}}^2 &= \frac{1}{n_1 + n_2 - 2} \sum_{i=1}^2 \sum_{j=1}^{n_i} (x_{ij\text{T}} - \bar{x}_{i\text{T}})^2 \\ \hat{\sigma}_{\text{TR}}^2 = s_{\text{BR}}^2 &= \frac{1}{n_1 + n_2 - 2} \sum_{i=1}^2 \sum_{j=1}^{n_i} (x_{ij\text{R}} - \bar{x}_{i\text{R}})^2\end{aligned}$$

where

$$\bar{x}_{i\text{T}} = \frac{1}{n_i} \sum_{j=1}^{n_i} x_{ij\text{T}} \quad \text{and} \quad \bar{x}_{i\text{R}} = \frac{1}{n_i} \sum_{j=1}^{n_i} x_{ij\text{R}}$$

Test for Equality

For testing the equality in total variability, consider the hypotheses in 34. Let $\eta = \sigma_{\text{TT}}^2 - \sigma_{\text{TR}}^2$. An intuitive estimator of η is given by

$$\hat{\eta} = \hat{\sigma}_{\text{TT}}^2 - \hat{\sigma}_{\text{TR}}^2$$

Let

$$s_{\text{BTR}}^2 = \frac{1}{n_1 + n_2 - 2} \sum_{i=1}^2 \sum_{j=1}^{n_i} (x_{ij\text{T}} - \bar{x}_{i\text{T}})(x_{ij\text{R}} - \bar{x}_{i\text{R}})$$

Let $\hat{\lambda}_1 < 0 < \hat{\lambda}_2$ be the two eigenvalues of the matrix $\Theta \hat{\Omega}_{\text{B}}$ where $\hat{\Omega}_{\text{B}}$ is defined in Eq. 26 and Θ is given in Eq. 27. A $(1 - \alpha) \times 100\%$ MLS confidence interval of η is given by

$$(\hat{\eta}_{\text{L}}, \hat{\eta}_{\text{U}})$$

where

$$\hat{\eta}_{\text{L}} = \hat{\eta} - \sqrt{\Delta_{\text{L}}}, \quad \hat{\eta}_{\text{U}} = \hat{\eta} + \sqrt{\Delta_{\text{U}}}$$

and

$$\begin{aligned}\Delta_{\text{L}} &= \hat{\lambda}_1^2 \left(1 - \frac{n_1 + n_2 - 2}{\chi_{1-\alpha/2, n_1+n_2-2}^2} \right)^2 + \hat{\lambda}_2^2 \left(1 - \frac{n_1 + n_2 - 2}{\chi_{\alpha/2, n_1+n_2-2}^2} \right)^2 \\ \Delta_{\text{U}} &= \hat{\lambda}_1^2 \left(1 - \frac{n_1 + n_2 - 2}{\chi_{\alpha/2, n_1+n_2-2}^2} \right)^2 + \hat{\lambda}_2^2 \left(1 - \frac{n_1 + n_2 - 2}{\chi_{1-\alpha/2, n_1+n_2-2}^2} \right)^2\end{aligned}$$

Test for Noninferiority/Superiority

Similar to testing intrasubject variabilities, consider the hypotheses in Eq. 35. For a given significance level of α , similarly, the $(1 - \alpha) \times 100\%$ upper confidence bound of $\eta = \sigma_{\text{TT}}^2 - \sigma_{\text{TR}}^2$ can be constructed as

$$\hat{\eta}_{\text{U}} = \hat{\eta} + \sqrt{\Delta_{\text{U}}}$$

where Δ_{U} is given by

$$\Delta_{\text{U}} = \hat{\lambda}_1^2 \left(\frac{n_1 + n_2 - 2}{\chi_{\alpha, n_1+n_2-2}^2} - 1 \right)^2 + \hat{\lambda}_2^2 \left(\frac{n_1 + n_2 - 2}{\chi_{1-\alpha, n_1+n_2-2}^2} - 1 \right)^2$$

and $\hat{\lambda}_1 < 0 < \hat{\lambda}_2$ be the two eigenvalues of the matrix $\Theta \hat{\Omega}_{\text{B}}$ where Θ is given in Eq. 28. We then reject the null hypothesis at the α level of significance if $\eta_{\text{U}} < 0$.

Test for Similarity

For testing similarity, the hypotheses of interest are described in Eq. 33. We then reject the null hypothesis and conclude similarity at the α level of significance if both hypotheses in Eq. 33 are rejected with significance level α .

The test can be performed by constructing the $(1 - \alpha) \times 100\%$ upper confidence bound of $\eta_1 = \sigma_{TT}^2 - \delta\sigma_{TR}^2$ and the $(1 - \alpha) \times 100\%$ lower confidence bound of $\eta_2 = \sigma_{TT}^2 - \delta\sigma_{TR}^2$ by the MLS method. For example, the $(1 - \alpha) \times 100\%$ lower confidence bound of η_2 is given by

$$\hat{\eta}_{2L} = \hat{\eta}_2 + \sqrt{\Delta_L}$$

where

$$\Delta_L = \hat{\lambda}_1^2 \left(1 - \frac{n_1 + n_2 - 2}{\chi_{1-\alpha, n_1+n_2-2}^2} \right)^2 + \hat{\lambda}_2^2 \left(1 - \frac{n_1 + n_2 - 2}{\chi_{\alpha, n_1+n_2-2}^2} \right)^2$$

where $\hat{\lambda}_1 < 0 < \hat{\lambda}_2$ are the two eigenvalues of the matrix $\Theta \hat{\Omega}_B$ where Θ is given in Eq. 29.

Replicated 2 x 2m Crossover Design

We can use a similar argument for the test of intersubject variabilities under model Eq. 8 with the estimators, for $k = T, R$,

$$\hat{\sigma}_{Tk}^2 = s_{Bk}^2 + \frac{m-1}{m} \hat{\sigma}_{wk}^2$$

where $\hat{s}_{Bk}^2$ and $\hat{\sigma}_{wk}^2$ are defined in Eq. 22 and Eq. 10, respectively.

Test for Equality

For testing the equality in total variability, consider the hypotheses in Eq. 34. An intuitive estimator of $\eta = \sigma_{TT}^2 - \sigma_{TR}^2$ is given by $\hat{\eta} = \hat{\sigma}_{TT}^2 - \hat{\sigma}_{TR}^2$. Let $\hat{\lambda}_1 < 0 < \hat{\lambda}_2$ be the two eigenvalues of the matrix $\Theta \hat{\Omega}_B$ where Θ is given in Eq. 27. By Lee et al.^[7], a $(1 - \alpha) \times 100\%$ confidence interval of η is given by

$$(\hat{\eta}_L, \hat{\eta}_U)$$

where

$$\hat{\eta}_L = \hat{\eta} - \sqrt{\Delta_L}, \quad \hat{\eta}_U = \hat{\eta} + \sqrt{\Delta_U}$$

and

$$\begin{aligned} \Delta_L = & \hat{\lambda}_1^2 \left(1 - \frac{n_s - 1}{\chi_{1-\alpha/2, n_s-1}^2} \right)^2 + \hat{\lambda}_2^2 \left(1 - \frac{n_s - 1}{\chi_{\alpha/2, n_s-1}^2} \right)^2 \\ & + \frac{(m-1)^2 \hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{\alpha/2, n_s(m-1)}^2} \right)^2 \\ & + \frac{(m-1)^2 \hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{1-\alpha/2, n_s(m-1)}^2} \right)^2 \end{aligned}$$

$$\begin{aligned} \Delta_U = & \hat{\lambda}_1^2 \left(1 - \frac{n_s - 1}{\chi_{\alpha/2, n_s-1}^2} \right)^2 + \hat{\lambda}_2^2 \left(1 - \frac{n_s - 1}{\chi_{1-\alpha/2, n_s-1}^2} \right)^2 \\ & + \frac{(m-1)^2 \hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{1-\alpha/2, n_s(m-1)}^2} \right)^2 \\ & + \frac{(m-1)^2 \hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{\alpha/2, n_s(m-1)}^2} \right)^2 \end{aligned}$$

We reject the null hypothesis at the α level of significance if $0 \notin (\hat{\eta}_L, \hat{\eta}_U)$.

Test for Noninferiority/Superiority

Consider a test of the hypotheses in Eq. 35. Let $\eta_2 = \sigma_{TT}^2 - \delta\sigma_{TR}^2$. For a given significance level of α , similarly, the $(1 - \alpha) \times 100\%$ upper confidence bound of η can be constructed as

$$\hat{\eta}_U = \hat{\eta} + \sqrt{\Delta_U}$$

where $\hat{\eta} = \hat{\sigma}_{TT}^2 - \delta\sigma_{TR}^2$ and Δ_U is given by

$$\begin{aligned} \Delta_U = & \hat{\lambda}_1^2 \left(1 - \frac{n_s - 1}{\chi_{\alpha, n_s-1}^2} \right)^2 + \hat{\lambda}_2^2 \left(1 - \frac{n_s - 1}{\chi_{1-\alpha, n_s-1}^2} \right)^2 \\ & + \frac{(m-1)^2 \hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{1-\alpha, n_s(m-1)}^2} \right)^2 \\ & + \frac{(m-1)^2 \hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{\alpha, n_s(m-1)}^2} \right)^2 \end{aligned}$$

where $n_s = n_1 + n_2 - 2$ and $\hat{\lambda}_1 < 0 < \hat{\lambda}_2$ are the eigenvalues of $\Theta \hat{\Omega}_B$ with Θ given in Eq. 28. We then reject the null hypothesis at the α level of significance if $\hat{\eta}_U$.

Test for Similarity

For testing similarity, the hypotheses of interest are described in Eq. 33. We then reject the null hypothesis and conclude similarity at the α level of significance if both hypotheses in Eq. 33 are rejected with significance level α . The test can be performed by constructing the $(1 - \alpha) \times 100\%$ upper confidence bound of $\eta_1 = \sigma_{TT}^2 - \delta\sigma_{TR}^2$ and the $(1 - \alpha) \times 100\%$ lower confidence bound of $\eta_2 = \sigma_{TT}^2 - \delta\sigma_{TR}^2$ by the MLS method. For example, the $(1 - \alpha) \times 100\%$ lower confidence bound of η_2 is given by

$$\hat{\eta}_{2L} = \hat{\eta}_2 - \sqrt{\Delta_L}$$

where

$$\Delta_L = \hat{\lambda}_1^2 \left(1 - \frac{n_s - 1}{\chi_{1-\alpha, n_s-1}^2} \right)^2 + \hat{\lambda}_2^2 \left(1 - \frac{n_s - 1}{\chi_{\alpha, n_s-1}^2} \right)^2 \\ + \frac{(m-1)^2 \hat{\sigma}_{WT}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{\alpha, n_s(m-1)}^2} \right)^2 \\ + \frac{(m-1)^2 \hat{\sigma}_{WR}^4}{m^2} \left(1 - \frac{n_s(m-1)}{\chi_{1-\alpha, n_s(m-1)}^2} \right)^2$$

where $\hat{\lambda}_1 < 0 < \hat{\lambda}_2$ be the two eigenvalues of the matrix $\Theta \hat{\Omega}_B$ where Θ is given in Eq. 29.

SAMPLE SIZE CALCULATION

For clinical scientists/biostatisticians, a great concern is how many subjects should be recruited in the clinical trial to achieve the desired power of statistical test, which is used to show equality, superiority, or similarity of the test formulation. If an explicit power function of a test is not available or difficult to obtain, sample size calculation depends on asymptotic power, which is usually obtained by using the central limit theorem. Also, some assumption about unknown parameters should be made to calculate sample size. These assumptions may come from previous or related clinical studies that can provide reasonable estimates for unknown parameters. If information about parameters is not available, it is common to assume the worst-case scenario so that sample size is big enough to assure that a clinical study will not fail to achieve its objective. In practice, however, it is difficult to obtain a large sample size because a clinical study is restricted by time and budget. Here, we introduce some statistical techniques to calculate sample size for comparing variabilities to achieve a desired power under some assumption about unknown parameters.

Sample Size for *F*-Test: Comparing Intrasubject Variabilities

If a test is based on *F* distribution, the explicit power function can be obtained so that fairly accurate sample size can be provided. Also, for most cases, the target sample size is available as an implicit solution of the equation so that no explicit formula for sample size is available. However, the target sample size can be obtained by numerical methods such as the grid search method or Newton–Raphson algorithm.

First, consider the hypotheses in Eq. 4 for test for equality of intrasubject variabilities under a parallel design with replicates in “Parallel Design with Replicates” under the section “Comparing Intrasubject Variabilities.” Under the alternative hypothesis, without loss of generality, we assume that $\sigma_{WT}^2 < \sigma_{WR}^2$. The power of the test can then be approximated by

$$1 - \beta = P(T < F_{1-\alpha/2, n_T(m-1), n_R(m-1)}) \\ = P(1/T > F_{\alpha/2, n_R(m-1), n_T(m-1)}) \\ = P\left(\frac{\hat{\sigma}_{WR}^2 / \sigma_{WR}^2}{\hat{\sigma}_{WT}^2 / \sigma_{WT}^2} > \frac{\sigma_{WT}^2}{\sigma_{WR}^2} F_{\alpha/2, n_R(m-1), n_T(m-1)}\right) \\ = P\left(F_{(n_R(m-1), n_T(m-1))} > \frac{\sigma_{WT}^2}{\sigma_{WR}^2} F_{\alpha/2, n_R(m-1), n_T(m-1)}\right)$$

where $F_{(a,b)}$ denotes an *F* random variable with *a* and *b* degrees of freedom. Under the assumption that $n = n_R = n_T$ and with a fixed value for *m*, σ_{WT}^2 , and σ_{WR}^2 , the sample size needed to achieve a desired power of $1 - \beta$ can be obtained by solving the following equation for *n*:

$$\frac{\sigma_{WT}^2}{\sigma_{WR}^2} = \frac{F_{1-\beta, n(m-1), n(m-1)}}{F_{\alpha/2, n(m-1), n(m-1)}}$$

Next, consider the hypotheses in Eq. 6 for the test for similarity of intrasubject variabilities under a parallel design with replicates. Assuming that $n = n_T = n_R$, under the alternative hypothesis that $\sigma_{WT}^2 = \sigma_{WR}^2$, the power of the test can be approximated by

$$1 - \beta = P\left(\frac{F_{\alpha, n(m-1), n(m-1)}}{\delta} < \frac{\hat{\sigma}_{WT}^2}{\hat{\sigma}_{WR}^2} < \delta F_{1-\alpha, n(m-1), n(m-1)}\right) \\ = P\left(\frac{1}{F_{\alpha, n(m-1), n(m-1)}} < \frac{\hat{\sigma}_{WT}^2}{\delta \hat{\sigma}_{WR}^2} < \delta F_{1-\alpha, n(m-1), n(m-1)}\right) \\ = 1 - 2P\left(\frac{\hat{\sigma}_{WT}^2}{\hat{\sigma}_{WR}^2} > \delta F_{1-\alpha, n(m-1), n(m-1)}\right) \\ = 1 - 2P\left(F_{(n(m-1), n(m-1))} > \delta F_{1-\alpha, n(m-1), n(m-1)}\right)$$

Thus, the sample size required for achieving a desired power of $1 - \beta$ can be obtained by solving the following equation for *n*

$$\delta = \frac{F_{\beta/2, n(m-1), n(m-1)}}{F_{1-\alpha, n(m-1), n(m-1)}}$$

Note that under the alternative hypothesis, it is also possible that $\sigma_{WT}^2 \neq \sigma_{WR}^2$. Without loss of generality, we assume that $\sigma_{WT}^2 / \sigma_{WR}^2 = r \in (1, \delta)$. In this case, the power of the above test can be approximated by

$$1 - \beta = P\left(\frac{F_{\alpha, n(m-1), n(m-1)}}{\delta} < \frac{\hat{\sigma}_{WT}^2}{\hat{\sigma}_{WR}^2} < \delta F_{1-\alpha, n(m-1), n(m-1)}\right) \\ \approx P\left(\frac{\hat{\sigma}_{WT}^2}{\hat{\sigma}_{WR}^2} < \delta F_{1-\alpha, n(m-1), n(m-1)}\right) \\ = P\left(\frac{\hat{\sigma}_{WT}^2}{r \hat{\sigma}_{WR}^2} < \frac{\delta}{r} F_{1-\alpha, n(m-1), n(m-1)}\right) \\ = P\left(F_{(n(m-1), n(m-1))} < \frac{\delta}{r} F_{1-\alpha, n(m-1), n(m-1)}\right)$$

Hence, the sample size needed to achieve the desired power of $1 - \beta$ can be obtained by solving the following equation for n :

$$\frac{\delta}{r} = \frac{F_{\beta, n(m-1), n(m-1)}}{F_{1-\alpha, n(m-1), n(m-1)}}$$

Sample Size for Z-Test: Comparing Intrasubject Coefficients of Variation

If a test is already based on the normal approximation of the test statistic, then sample size can be easily obtained by simple calculation of power function, which is based on the normal distribution. In this case, the explicit form of target sample size is usually available.

Here, we consider the test for comparing intrasubject CVs under the section “Simple Random Effects Model.” First, consider the hypothesis in Eq. 11 for the test of equality of intrasubject CVs. Under the alternative hypothesis, without loss of generality, it is assumed that $CV_T > CV_R$. The distribution of test statistics can be approximated by a normal distribution with unit variance and mean

$$\frac{CV_T - CV_R}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}}$$

Thus, the power is given by

$$\begin{aligned} 1 - \beta &= P(|T| > z_{\alpha/2}) \approx P(T > z_{\alpha/2}) \\ &= P\left(N(0,1) > z_{\alpha/2} - \frac{CV_T - CV_R}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}}\right) \end{aligned}$$

Under the assumption that $n = n_1 = n_2$, the sample size needed to have a power of $1 - \beta$ can be obtained by solving the following equation

$$z_{\alpha/2} - \frac{CV_T - CV_R}{\sqrt{\sigma_T^{*2}/n + \sigma_R^{*2}/n}} = -z_\beta$$

This leads to

$$n = \frac{(\sigma_T^{*2} + \sigma_R^{*2})(z_{\alpha/2} + z_\beta)^2}{(CV_T - CV_R)^2}$$

Next, consider the hypothesis in Eq. 13 for the test of similarity of intrasubject CVs under simple random effects model. Under the alternative hypothesis that $CV_T = CV_R$, the power of the test procedure is given by

$$\begin{aligned} 1 - \beta &= P\left(z_\alpha - \frac{\delta}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}}\right. \\ &\quad \left.< N(0,1) < \frac{\delta}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}} - z_\alpha\right) \\ &= 1 - 2P\left(N(0,1) > \frac{\delta}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}} - z_\alpha\right) \end{aligned}$$

Hence, under the assumption that $n = n_1 = n_2$, the sample size needed to achieve $1 - \beta$ power at the α level of significance can be obtained by solving the following equation

$$\frac{\delta}{\sqrt{\sigma_T^{*2}/n + \sigma_R^{*2}/n}} - z_\alpha = z_{\beta/2}$$

This leads to

$$n = \frac{(z_\alpha + z_{\beta/2})^2(\sigma_T^{*2} + \sigma_R^{*2})}{\delta^2}$$

Under the alternative, without loss of generality, we assume that $0 < CV_T - CV_R < \delta$. Then, the power of the test procedure can be approximated by

$$\begin{aligned} 1 - \beta &= P\left(z_\alpha - \frac{\delta + |CV_T - CV_R|}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}} < N(0,1)\right. \\ &\quad \left.< \frac{\delta - |CV_T - CV_R|}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}} - z_\alpha\right) \\ &\approx P\left(N(0,1) < \frac{\delta - |CV_T - CV_R|}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}} - z_\alpha\right) \end{aligned}$$

Hence, under the assumption that $n = n_1 = n_2$, the sample size needed to achieve $1 - \beta$ power at the α level of significance can be obtained by solving the following equation

$$\frac{\delta - |CV_T - CV_R|}{\sqrt{\sigma_T^{*2}/n_T + \sigma_R^{*2}/n_R}} - z_\alpha = z_\beta$$

This gives

$$n = \frac{(z_\alpha + z_\beta)^2(\sigma_T^{*2} + \sigma_R^{*2})}{(\delta - |CV_T - CV_R|)^2}$$

Sample Size for Modified Large Sample Method: Comparing Intersubject Variabilities

If a test is based on the MLS method, the explicit power function is difficult to calculate so that approximated power function should be obtained by using CLT to find the target sample size. The crucial step for normal approximation is the calculation of the asymptotic variance of a test statistic. The asymptotic variance of test statistics based on the MLS method can be easily calculated because estimators of variance components are usually distributed as chi-square distribution. When estimators of variance components are not independent, the asymptotic variance can be easily obtained via the eigenvalues of $\Theta\Omega_B$ where Ω_B is a 2×2 intersubject covariance matrix and Θ is some 2×2 matrix.

We will consider the test of intersubject variabilities in “Parallel Design Replicates” under the section “Comparing Intersubject Variabilities.” Consider the hypothesis in Eq. 11 for the test of equality of intersubject variabilities. Under the alternative hypothesis, without loss of generality, we assume that $\sigma_{BR}^2 > \sigma_{BT}^2$ and $n = n_T = n_R$. Thus, the power of the test procedure can be approximated by

$$P\left(N\left(\frac{\sqrt{n}(\sigma_{BR}^2 - \sigma_{BT}^2)}{\sigma^*}, 1\right) > z_{\alpha/2}\right)$$

where asymptotic variance σ^* of the test statistic is given by

$$\sigma^{*2} = 2\left[\left(\sigma_{BT}^2 + \frac{\sigma_{WT}^2}{m}\right)^2 + \left(\sigma_{BR}^2 + \frac{\sigma_{WR}^2}{m}\right)^2 + \frac{\sigma_{WT}^4}{m^2(m-1)} + \frac{\sigma_{WR}^4}{m^2(m-1)}\right]$$

Because a parallel design is used, the estimators of variance components are independent so that asymptotic variance σ^{*2} can be obtained by using variance of chi-square random variable. As a result, the sample size needed to achieve the desired power of $1 - \beta$ at the α level of significance can be obtained by solving the following equation

$$z_{\alpha/2} - \frac{\sqrt{n}(\sigma_{BT}^2 - \sigma_{BR}^2)}{\sigma^*} = -z_{\beta}$$

This leads to

$$n = \frac{\sigma^{*2}(z_{\alpha/2} + z_{\beta})^2}{(\sigma_{BT}^2 - \sigma_{BR}^2)^2}$$

Now consider the test of equality of total variabilities under the section “Standard 2×2 Crossover Design.” Here, the test is based on the MLS method and estimators of variance components are not independent. Under the alternative hypothesis and letting $n = n_1 + n_2 - 2$, without loss of generality, we assume $\sigma_{TR}^2 > \sigma_{TT}^2$. The power of the above test can be determined by

$$P\left(N\left(\frac{\sqrt{n}(\sigma_{TT}^2 - \sigma_{TR}^2)}{\sigma^*}, 1\right) > z_{\alpha/2}\right)$$

where

$$\sigma^{*2} = 2(\lambda_1^2 + \lambda_2^2) \equiv 2(\sigma_{TT}^4 + \sigma_{TR}^4 - 2\rho^2\sigma_{BT}^2\sigma_{BR}^2)$$

where let $\lambda_1 < 0 < \lambda_2$ are the two eigenvalues of the matrix $\Theta\Omega_B$ where Ω_B is defined in Eq. 25 and Θ is given in Eq. 27.

Hence, the sample size needed to achieve the power of $1 - \beta$ at the α level of significance can be obtained by solving the following equation

$$z_{\alpha/2} = -\frac{\sqrt{n}(\sigma_{TT}^2 - \sigma_{TR}^2)}{\sigma^*} = -z_{\beta}$$

which implies that

$$n = \frac{\sigma^{*2}(z_{\alpha/2} + z_{\beta})^2}{(\sigma_{TT}^2 - \sigma_{TR}^2)^2}$$

CONCLUSION

For comparing intrasubject variabilities and/or intrasubject CVs between treatment groups, replicates from the same subject are essential regardless of the study design. In clinical research, data are often log-transformed before the analysis. It should be noted that the intrasubject standard deviation of log-transformed data is approximately equal to the intrasubject CV of the untransformed (raw) data. As a result, it is suggested that intrasubject variability be used when analyzing log-transformed data and the intrasubject CV be considered when analyzing untransformed data.

In recent years, the assessment of reproducibility in terms of intrasubject variability or intrasubject CV in clinical research has received much attention. Chow^[11] defined reproducibility of a study drug as a collective term that encompasses consistency, similarity, and stability (control) within the therapeutic index (or window) of a subject's clinical status (e.g., clinical response of some primary study endpoint, blood levels, or blood concentration–time curve) when the study drug is repeatedly administered at different dosing periods under the same experimental condition. Reproducibility of clinical results observed from a clinical study can be quantitated through the evaluation of the so-called reproducibility probability, which will be briefly introduced.^[12]

For assessment of intersubject variability and/or total variability, Chow and Tse^[13] indicated that the usual analysis of variance model could lead to negative estimates of the variance components, especially the intersubject variance component. In addition, the sum of the best estimates of the intrasubject variance and the intersubject variance may not lead to the best estimate for the total variance. Chow and Shao^[14] proposed an estimation procedure for variance components, which cannot only avoid negative estimates but can also provide a better estimate than the maximum likelihood estimates. For estimation of total variance, Chow and Tse^[13] proposed a method as an alternative to the sum of estimates of individual variance components. These ideas could be applied to provide a better estimate of sample sizes for studies intended for comparing variabilities between treatment groups.

Abstract

This entry discusses some of the commonly used outlier detection techniques in clinical research, discussing methods of detection in normally distributed data, in generalized linear mixed models, and in crossover models.

INTRODUCTION

In clinical studies, detection of potential outlying observations is a critical step in the data analysis process before reaching any final conclusion of the study. The presence of outlying observations can affect the results of an analysis. In particular, it is possible that a totally opposite conclusion can be reached in marginal cases depending on the inclusion or exclusion of outlying observations. A bioavailability analysis that includes the possible outlying observations may lead to the rejection of bioequivalence when, in fact, the formulations are bioequivalent. Furthermore, outlying observations are often presented in the form of extremely large and/or small values. The inclusion of extreme values would inevitably increase the estimate of the variability. Large estimate of variability would affect the sensitivity of the statistical methodology in the detection of clinical difference. It is necessary to examine critically the presence of outlying observations in a data set. Thus, the study of outlier detection has received much attention in the literature. Many techniques have been proposed for the detection of outlying observations under different settings. This entry discusses some of the commonly used outlier detection techniques in clinical research.

Section “Detection of Outlier in Normally Distributed Data” reviews the statistical tests for the detection of outliers when data are normally distributed. The discussion is then extended to methods which are applicable to the regression settings such that the responses are dependent on one or several explanatory variables. Section “Detection of Outlier in Crossover Model” is focused on crossover models which are common designs in clinical study for assessing bioequivalence among several formulations. Statistical tests for detecting outlying subjects and observations within a given formulation will be outlined. Section “Outlier Detection Under Generalized Linear Mixed Models” discusses the detection of outliers in generalized linear mixed models (GLMM). GLMM is an extension of

the linear mixed models (LMM) and generalized linear models (GLM). It provides more general structure to study correlated data in a clinical study where data are collected from the same cluster or repeated measures resulting from a longitudinal study. An example is given in the section “An Example” to demonstrate the proposed detection procedure. Some concluding remarks are provided in the last section of this article.

DETECTION OF OUTLIER IN NORMALLY DISTRIBUTED DATA

Test for Extreme Values

Data from clinical studies are often assumed to be approximately normally distributed. The validity of the analysis is in doubt if the extreme observation(s), either too large or too small, is (are) included in the analysis. A statistical test proposed by Dixon^[1] can be used to determine whether the extreme value(s) should be deleted in the analysis.^[1] Suppose that $Y_1, Y_2, \dots, Y_n$ are n observations collected from a study. These observations are sorted ascendingly according to their magnitude and are denoted as $Y_{(1)}, Y_{(2)}, \dots, Y_{(n)}$, where $Y_{(1)}$ is the smallest value and $Y_{(n)}$ is the largest. For different values of sample size n , Dixon proposed criteria for the detection of outlying values and tabulated the corresponding critical values at significance level $\alpha = 5\%$ and 1% . For example, if the sample size n is between 14 and 25, the ratio r , defined in the following, is considered

$$r = \begin{cases} \frac{Y_{(3)} - Y_{(1)}}{Y_{(n-2)} - Y_{(1)}} & \text{if the smallest value is suspected} \\ & \text{to be outlier} \\ \frac{Y_{(n)} - Y_{(n-2)}}{Y_{(n)} - Y_{(3)}} & \text{if the largest value is suspected} \\ & \text{to be outlier} \end{cases} \quad (1)$$

This ratio r , which depends on the sample size n , is compared to appropriate tabulated values and the corresponding suspected value is considered to be an outlier if the ratio r is greater than or equal to the tabulated value. In particular, the expression (1) for r is different for different ranges of values of the sample size n . Details can be found in Dixon.^[1]

An alternative method to detect outliers for normally distributed data is the so-called T method, which is based on the standardized distance of the extreme observation from the mean of the sample. In particular, the standardized distance d is defined as $d = \frac{Y_n - \bar{Y}}{S}$ where Y_n is the extreme value, $\bar{Y}$ is the mean and S is the standard deviation of the n observations. For a given sample size n and significance level α , the extreme value is identified as an outlier if d is equal to or exceeds the corresponding critical value. Critical values for various n and $\alpha = 5\%$ are tabulated in Bolton.^[2]

Test for Residuals in Regression Models

Data collected from a clinical study can often be described by a regression model where the response Y is dependent on a set of p covariates $x_{1j}, x_{2j}, \dots, x_{pj}, j = 1, 2, \dots, n$. Thus, a multiple linear regression model $Y = X\beta + \varepsilon$ is considered, where Y is an $n \times 1$ vector of responses, X is an $n \times (p + 1)$ matrix representing the p covariates, β is an $(p + 1) \times 1$ vector of unknown parameters, and ε is an $n \times 1$ vector of random errors. In particular, the random errors are independently and normally distributed with mean 0 and variance σ^2 . Residuals, which are the differences between the fitted responses and the observed responses, resulting from the least squares estimation of the unknown parameters are given by $e = Y - X(X'X)^{-1}X'Y$. Many techniques proposed for the detection of outliers in the linear regression model are based on the examination of these residuals or the corresponding Studentized residuals, which is the ratio of the residual to its standard error. Reviews of these techniques can be found in Cook and Weisberg, Chatterjee and Hadi.^[3,4] In particular, Lund^[5] proposed an outlier detection method based on the Studentized residuals.^[5] The idea is to use a second order Bonferroni inequality to obtain upper and lower bounds for the probability of the maximum Studentized residuals exceeding a critical value. Tables of critical values for test at levels $\alpha = 0.01, 0.05$, and 0.1 are given in Lund.^[5] The U.S. Food and Drug Administration (FDA) has recommended using these results to identify outliers if data are fitted in a multiple linear regression model.

However, the methods discussed above are useful only in a multiple linear regression setting that requires statistical independence of all pharmacokinetic responses. In many clinical studies, it is quite common to adopt a crossover design for assessing bioequivalence among several formulations. Lund's method is not appropriate for a design in which the responses from the same subject are correlated.

Discussion in the following sections is focused on methods that are applicable to cases when data are correlated.

DETECTION OF OUTLIER IN CROSSEVER MODEL

In many clinical studies, a crossover method is adopted to study the bioequivalence of several formulations of a drug. Observations from the same subject are correlated and do not fit into the framework of a linear regression model. Therefore, it is necessary to consider other techniques for the detection of outlying observations under this correlated setting. Consider the following crossover model:

$$Y_{ijk} = \mu + S_i + F_j + P_k + \varepsilon_{ijk} \quad (2)$$

$$j, k = 1, \dots, n; i = 1, \dots, m$$

where Y_{ijk} is the response variable on the i th subject in the k th period under the j th formulation, μ is the overall mean; S_i is the random effect of the i th subject; F_j is the fixed effect of the j th formulation; P_k is the fixed effect of the k th period; and ε_{ijk} is the error term. In particular, we assume that the fixed effects F_j and P_k satisfy the conditions that $\sum_{j=1}^n F_j = 0$ and $\sum_{k=1}^n P_k = 0$; the random subject effects S_i and the errors ε_{ijk} are independently and normally distributed with mean 0 and variances σ_a^2 and σ_e^2 , respectively. In Eq. (2), the sequence effect is pooled together with the subject effect, i.e., S_i comprises the “between sequences” and “subjects within sequence” effects. In a bioavailability/bioequivalence study, the distribution of the response variable of primary interest is often skewed. Thus, these responses are often applied with a log transformation to remove the skewness and then the transformed data are analyzed using Eq. (2).

Likelihood Distance Test

In bioavailability studies, some subjects may exhibit extremely high or low bioavailability with respect to the reference formulation. These extreme observations indicate that the variability of subject responses to a formulation is not homogeneous and they may induce dramatic effects on the bioequivalence test. Chow and Tse^[6] have proposed a procedure based on the idea of likelihood distance to detect potential outlying subject.^[6] To highlight the essence of their approach, the discussion is focused on a simplified model of (2) with the assumption that there are no period and formulation effects. Then, Eq. (2) reduces to

$$Y_{ij} = \mu + S_i + \varepsilon_{ij} \quad j = 1, 2, \dots, n; \quad i = 1, 2, \dots, m. \quad (3)$$

The parameters associated with this reduced model are μ , σ_a^2 , and σ_e^2 . The log-likelihood function $L(\mu, \sigma_a^2, \sigma_e^2)$ is

$$L(\mu, \sigma_a^2, \sigma_e^2) = -\frac{mn}{2} \log 2\pi - \frac{m}{2} \log(\sigma_e^2 + n\sigma_a^2)(\sigma_e^2)^{n-1} \\ - \frac{1}{2\sigma_e^2} \sum_{i=1}^m \sum_{j=1}^n (Y_{ij} - \mu)^2 \quad (4) \\ - \frac{n}{2} \left(\frac{1}{\sigma_e^2 + n\sigma_a^2} - \frac{1}{\sigma_e^2} \right) \sum_{i=1}^m (\bar{Y}_i - \mu)^2.$$

The maximum likelihood estimators (MLE) of μ , σ_a^2 and σ_e^2 can be found by maximizing (4) with respect to the parameters and are given by

$$\hat{\mu} = \bar{Y} = \frac{1}{nm} \sum_{i=1}^m \sum_{j=1}^n Y_{ij} \\ \hat{\sigma}_e^2 = \frac{1}{m(n-1)} \sum_{i=1}^m \sum_{j=1}^n (Y_{ij} - \bar{Y}_i)^2 \text{ with } \bar{Y}_i = \frac{1}{n} \sum_{j=1}^n Y_{ij} \\ \hat{\sigma}_a^2 = \frac{1}{n} \left\{ \frac{n}{m} \sum_{i=1}^m (\bar{Y}_i - \bar{Y})^2 - \frac{1}{m(n-1)} \sum_{i=1}^m \sum_{j=1}^n (Y_{ij} - \bar{Y}_i)^2 \right\}$$

If $\frac{n}{m} \sum_{i=1}^m (\bar{Y}_i - \bar{Y})^2 < \frac{1}{m(n-1)} \sum_{i=1}^m \sum_{j=1}^n (Y_{ij} - \bar{Y}_i)^2$, then the maximum likelihood estimators of σ_a^2 and σ_e^2 are derived by maximizing $L(\mu, \sigma_a^2, \sigma_e^2)$ under the condition that $\sigma_a^2 \geq 0$. Thus, the resulting MLEs are modified to $\hat{\mu} = \bar{Y}$, $\hat{\sigma}_e^2 = \frac{1}{nm} \sum_{i=1}^m \sum_{j=1}^n (Y_{ij} - \bar{Y})^2$ and $\hat{\sigma}_a^2 = 0$.

The likelihood distance test is based on Cook and Weisberg's idea of likelihood distance to identify an outlying subject. Let $\theta = (\mu, \sigma_e^2, \sigma_a^2)$ be the parameter vector. Because the log-likelihood function $L(\theta)$ provides a summary of the information concerning for a given data set, we calculate the influence of the i th case based on the difference of the log-likelihood between $\hat{\theta}$ and $\hat{\theta}_{(-i)}$, where $\hat{\theta}_{(-i)}$ denotes the MLE of θ with deletion of the i th subject. Thus, the difference $L(\hat{\theta}) - L(\hat{\theta}_{(-i)})$ measures the influence of the i th subject of the given data set. If the difference is large, we consider the i th subject as an outlier. Furthermore, the statistic, which is based on the log-likelihood distance,

$$LD_i(\hat{\theta}) = 2[L(\hat{\theta}) - L(\hat{\theta}_{(-i)})] \quad (5)$$

is asymptotically chi-square distributed with 3 degrees of freedom as the number of subjects $m \rightarrow \infty$. Thus, we consider the i th subject as an outlier if

$$LD_i(\hat{\theta}) > \chi_3^2(\alpha) \quad (6)$$

where $\chi_3^2(\alpha)$ is the upper α percentage point of χ_3^2 .

Though the discussion above is based on the assumption that the period effects P_k and the formulation effects F_j are not presented in the model, the idea can be easily

generalized to cases including these effects. Under Eq. (2), the MLE of the period effects and the formulation effects are given by $\hat{P}_k = \frac{1}{mn} \sum_{i=1}^m \sum_{j=1}^n Y_{ijk} - \bar{Y}$ and $\hat{F}_j = \frac{1}{mn} \sum_{i=1}^m \sum_{k=1}^n Y_{ijk} - \bar{Y}$, where $\bar{Y} = \frac{1}{nm^2} \sum_{i=1}^m \sum_{j=1}^n \sum_{k=1}^n Y_{ijk}$. The above estimation process is repeated by deleting one subject at a time to obtain $\hat{P}_{k(-i)}$ and $\hat{F}_{j(-i)}$. For the likelihood distance method, we can find the likelihood distance LD_i by taking the difference between the likelihood functions evaluated with and without the i th subject. The resulting difference LD_i is asymptotically chi-square distributed with $3 + 2(n-1)$ degrees of freedom, where the degree of freedom is equal to the number of independent parameters estimated in the model. However, note that the distribution of likelihood distance is based on asymptotic reasoning. Thus, it would be a concern if the number of subjects, m , is relatively small. Further discussion on the distribution properties of the likelihood distance can be found in Wang, Chow, and Wei.^[7]

Test Based on Hotelling T^2 Statistic

An alternative approach for outlier detection under Eq. (3) was proposed by Liu and Weng.^[8] Their idea was based on the order statistics of the two-sample Hotelling T^2 statistics. Let $Y'_i = (Y'_{i1}, \dots, Y'_{in})$ be the vector of responses. Then Y'_i is multivariate normally distributed with mean vector $\mu' = (\mu + S_1, \mu + S_2, \dots, \mu + S_m) = (\mu_1, \dots, \mu_m)$ and covariance matrix Σ with diagonal elements $\sigma_a^2 + \sigma_e^2$ and off-diagonal elements σ_a^2 .

Suppose that the i th subject is suspected to have a shift in the location. The hypotheses for the detection of this outlying subject are given as

$$H_0: Y'_i \sim N(\mu, \Sigma), \quad \text{for all } i = 1, 2, \dots, m \\ H_1: Y'_i \sim N(\mu + \Delta_i, \Sigma), \quad \text{for at least one } i \quad (7)$$

Equivalently, these hypotheses can be decomposed into m subhypotheses:

$$H_{0i}: Y'_i \sim N(\mu, \Sigma) \text{ vs } H_{1i}: Y'_i \sim N(\mu + \Delta_i, \Sigma), \\ \text{where } i = 1, 2, \dots, m. \quad (8)$$

The definition of (7) and (8) implies that $H_0 = \bigcap_{i=1}^m H_{0i}$ and $H_1 = \bigcup_{i=1}^m H_{1i}$. Denote T_i^2 to be the Hotelling T^2 statistic for the i th subject, then

$$T_i^2 = \frac{(m-1)(m-2)}{m} (Y'_i - \bar{Y}_{(-i)})' A_{(-i)}^{-1} (Y'_i - \bar{Y}_{(-i)}) \\ = \frac{(m-2)(Y'_i - \bar{Y})' A^{-1} (Y'_i - \bar{Y})}{\left[\frac{m-1}{m} - (Y'_i - \bar{Y})' A^{-1} (Y'_i - \bar{Y}) \right]} \quad (9)$$

where $\bar{Y}$ and A are the sample mean vector and matrix of sums of squares and cross products computed from the

responses $Y_i, \dots, Y_m$ respectively; and $\bar{Y}_{(-i)}$ and $A_{(-i)}$ are the similar statistics computed without the i th subject. Then, hypotheses (8) can be tested using test statistic T_i^2 given in (9) with the sequential step-down testing procedure to detect possible multiple outlying subjects. Details of this test procedure can be found in Liu and Weng.^[8] However, one difficulty associated with using this approach to detect outlying subjects is that the sampling distribution of the test statistic $T_{(i)}^2$ under the null hypothesis $H_{0(i)}$ is analytically intractable. Alternatively, Liu and Weng^[8] used Monte Carlo simulation to give the 5% and 1% upper quantiles of the distribution of $T_{(i)}^2$ for $n = 2, 3$; $m = 10(1)20$ and $20(5)50$.^[8] For other combinations of n and m values encountered in practice, one has to rely on simulation to evaluate the corresponding sample distribution of the test statistic.

The results of the above two methods, based either on the likelihood distance or the Hotelling T^2 statistic, are for the detection of outlying subjects. Liu and Weng^[8] have discussed how to generalize their idea for the detection of outlying observations within a given formulation.^[8] Further details and examples can be found in Chow and Liu.^[9]

OUTLIER DETECTION UNDER GENERALIZED LINEAR MIXED MODELS

The linear multiple regression models discussed in section II are employed based on an assumption of independent responses. In many clinical studies, this assumption may be in doubt for data collected in clusters due to the design of the study. For example, responses of subjects from the same hospital are anticipated to be correlated, though the responses may be independent between hospitals. Thus, each hospital is considered to be a cluster and the analysis has to take into account of the correlation of data from the same cluster. Besides, individual subject may be measured repeatedly over time after a treatment is applied. For a given subject, the measurements observed in such a longitudinal study are correlated across time but independent between subjects. Hence, the data can be regarded as clustered data for individual subject. The development of the GLMM was motivated by the need of fitting clustered data described in the above situations, in which the correlation within clusters is incorporated by the random effects in the model. Unlike ordinary linear regression, the GLMM can fit data from a broad distribution family, namely, the exponential distribution family, which includes normal distribution as a special case.

Formulation of GLMM

The GLMM for N clustered responses Y from the exponential family conditional on random effects u is defined by

$$Y | u \sim f_{y|u}(Y | u, \beta, \phi) = \exp\{\phi[Y'\eta - b(\eta) - c(Y)] - s(Y, \phi)\}. \quad (10)$$

Here the random effects u are assumed to be multivariate normally distributed, $u \sim N(0, \sigma^2 D)$ where $\sigma^2 (> 0)$ is an unknown parameter and D is a known non-negative definite matrix. The conditional expectation of Y given u is connected to a linear predictor η through a link function $g(\cdot)$, that is, $g(E(Y | u)) = \eta$ with $\eta = X\beta + Zu$. Here, X and Z are known design matrices corresponding to fixed effects β and random effects u , respectively. Each u_j has n_j components ($N = \sum_{j=1}^q n_j$), distributed as $N(0, \sigma^2 D_j)$ with a known covariance matrix D_j , and is independent of each other for $j = 1, \dots, q$. Hence, D may be expressed as $D = \text{diag}(D_1, D_2, \dots, D_q)$. The best linear unbiased predictor (BLUP) type joint log-likelihood of parameters β, u, σ^2 and ϕ is then defined as $l = l_1 + l_2$ with

$$l_1 = \ln f(Y; \beta | u) = \phi[Y'\eta - b(\eta) - c(Y)] - s(Y, \phi)$$

$$l_2 = \ln \phi(u | D) = -\frac{1}{2} \sum_{j=1}^q [n_j \log(2\pi\sigma^2) + \log |D_j| + u_j' D_j^{-1} u_j], \quad (11)$$

The approximate maximum likelihood estimates $\hat{\beta}, \hat{u}, \hat{\sigma}^2$, and $\hat{\phi}$ are obtained by maximizing l . Details can be found in McGilchrist.^[10]

Detection of Outlying Observations

Various approaches have been proposed to detect outlying observation(s) that may impact on model fitting and/or statistical inferences for the assumed statistical model, including case-deletion and mean-shift outlier models; see, e.g., Cook and Weisberg,^[3] Chatterjee and Hadi,^[4] and Atkinson.^[11] Among them, case-deletion is the most popular approach to identify such anomalous observations due to its intuition and simplicity. If an observation is deleted and the model refitted, the parameter estimates will change. The case-deletion approach, known as deletion diagnostics, uses formulae to judge such changes of the inference. Traditionally, the focus of deletion diagnostics is on the effects of removing an individual observation or a case. Since GLMM is appropriate for analyzing subgroups of correlated responses, it is natural to consider deletion in the context of a cluster. Therefore, the effects of outlying clusters and/or observations on parameter estimates are of interest in the GLMM setting.

In particular, the importance of the deletion of the k th cluster is judged by Cook's distance, defined generally by

$$CD_k = (\hat{\beta} - \hat{\beta}_{(k)})' \text{Cov}^{-1}(\hat{\beta})(\hat{\beta} - \hat{\beta}_{(k)}) \quad (12)$$

where $\hat{\beta}$ and $\hat{\beta}_{(k)}$ denote the estimates of β with and without the k th cluster, respectively. Cook's distance is a measure the difference between $\hat{\beta}$ and $\hat{\beta}_{(k)}$. Large values of Cook's distance correspond to "outlying" clusters.

To investigate the change of deleting a cluster of correlated observations on the estimator $\hat{\beta}$, there is no exact expression for such change provided by CD_k in the GLMM setting. Therefore, a first-order approximation to $\hat{\beta}$ with the k th cluster deleted is considered which would facilitate the derivation of an approximate Cook's distance CD_k . This approximate CD_k is computationally efficient because it avoids repeated refitting of the model after the deletion of the k th cluster. Pregibon^[12] has investigated this idea of using the first-order approximation in the GLM case.^[12]

Denote $\hat{\beta}_{(k)}$, $\hat{u}_{j(k)}$, and $\hat{\sigma}_{(k)}^2$ as the respective maximum likelihood estimators of β , u_j , and σ^2 after removing observations of the k th cluster. Since u_j 's are assumed to be mutually independent, deleting the k th cluster should not affect the estimator of u_j for $j \neq k$. The focus is thus on $\hat{\beta}_{(k)}$, treating u_j , σ^2 and ϕ as nuisance parameters. Let $\dot{l}(\hat{\beta})$ and $\ddot{l}(\hat{\beta})$ represent respectively the first-order and second-order derivatives of the log-likelihood l , defined in (11), with respect to β evaluated at $\beta = \hat{\beta}$. If $l_{1(k)}$ denotes the log-likelihood l_1 based on data without the k th cluster, then $\dot{l}_{1(k)}(\hat{\beta}_{(k)}) = 0$. Consider the first-order Taylor expansion of $\dot{l}_{1(k)}(\hat{\beta}_{(k)})$ at $\hat{\beta}$, then

$$\dot{l}_{1(k)}(\hat{\beta}) + \ddot{l}_{1(k)}(\hat{\beta})(\hat{\beta} - \hat{\beta}_{(k)}) \approx 0. \quad (13)$$

To simplify presentation, let $E = Y - \mu$ and $B = -a(\phi) \frac{\partial^2 l}{\partial \eta \partial \eta'} = \frac{\partial^2 c(\eta)}{\partial \eta \partial \eta'}$. Since the clusters are assumed to be mutually independent, $B = \text{diag}(B_1, B_2, \dots, B_q)$ is a block diagonal matrix with $n_j \times n_j$ component matrix B_j . Then,

$$\begin{aligned} \dot{l}_{1(k)}(\hat{\beta}) &= \left(\frac{\partial \eta_{1(k)}}{\partial \beta'} \right)' \cdot \frac{\partial l_{1(k)}}{\partial \eta_{(k)}} = a^{-1}(\phi) X'_{(k)} E_{(k)}, \\ \ddot{l}_{1(k)}(\hat{\beta}) &= \left(\frac{\partial \eta_{1(k)}}{\partial \beta'} \right)' \left(\frac{\partial^2 l_{1(k)}}{\partial \eta_{(k)} \partial \eta'_{(k)}} \right) \left(\frac{\partial \eta_{1(k)}}{\partial \beta'} \right) + \left(\frac{\partial l_{1(k)}}{\partial \eta_{(k)}} \right)' \left(\frac{\partial^2 \eta_{(k)}}{\partial \beta \partial \beta'} \right) \\ &= X'_{(k)} (-a^{-1}(\phi) B_{(k)}) X_{(k)} \end{aligned}$$

where the derivatives are evaluated at $\hat{\beta}$, $\hat{u}$ and $\hat{\phi}$. Rewrite X and E in partitioned matrix form as $X = (X'_1, \dots, X'_q)'$ and $E = (E'_1, \dots, E'_q)'$, with $n_j \times p$ component matrix X_j and $n_j \times 1$ component vector E_j corresponding to the j th cluster, for $j = 1, \dots, q$. From (13), after removing the k th cluster, the first-order approximate updating formula for $\hat{\beta}_{(k)}$ is

$$\hat{\beta}_{(k)} \approx \hat{\beta} - (\tilde{X}'\tilde{X})^{-1} \tilde{X}'(I - \tilde{H}_k)^{-1} \tilde{E}_k \quad (14)$$

where $\tilde{X} = B^{-\frac{1}{2}}X = (\tilde{X}'_1, \dots, \tilde{X}'_q)'$, $\tilde{X}_k = B_k^{-\frac{1}{2}}X_k$, $\tilde{E}_k = B_k^{-\frac{1}{2}}E_k$ and $\tilde{H}_k = \tilde{X}'_k(\tilde{X}'\tilde{X})^{-1}\tilde{X}_k$ for $k = 1, \dots, q$.

Note that the Cook's distance $CD_k(\hat{\beta})$ for assessing influence of the k th cluster on $\hat{\beta}$ in GLMM can be defined as $CD_k(\hat{\beta}) = (\hat{\beta} - \hat{\beta}_{(k)})'(-\ddot{l}(\hat{\beta}))(\hat{\beta} - \hat{\beta}_{(k)}) / (p \cdot a^{-1}(\hat{\phi}))$.

To facilitate computation, a first-order approximation to $CD_k(\hat{\beta})$ based on (14) is recommended by Xiang et al.:^[13]

$$CD_k(\hat{\beta}) \approx \tilde{E}'_k(I - \tilde{H}_k)^{-1} \tilde{H}_k(I - \tilde{H}_k)^{-1} \tilde{E}_k / p. \quad (15)$$

Results (14) and (15) are analogous to those for the linear regression model as discussed in Cook and Weisberg.^[3] Here $\tilde{E}_k$ is the residual vector associated with the k th cluster, and $\tilde{H}_k$ has a structure similar to that of the hat matrix in regression. Furthermore, if a subset of parameters is of interest, $CD_k(\hat{\beta})$ given in (15) can be modified accordingly through the corresponding partitioned matrix. In particular, to assess influence of the k th cluster on individual coefficient, the corresponding Cook's distance measure is

$$\begin{aligned} CD_k(\hat{\beta}_j) &= (\hat{\beta}_j - \hat{\beta}_{j(k)})'(-d'_j \ddot{l}^{-1}(\hat{\beta}) d_j)^{-1} (\hat{\beta}_j - \hat{\beta}_{j(k)}) / (a^{-1}(\hat{\phi})) \\ &\approx \tilde{E}'_k(I - \tilde{H}_k)^{-1} \tilde{X}_k \left[(\tilde{X}'\tilde{X})^{-1} - \begin{pmatrix} 0 & 0 \\ 0 & (\tilde{X}'_{(j)}\tilde{X}_{(j)})^{-1} \end{pmatrix} \right] \\ &\quad \times \tilde{X}'_k(I - \tilde{H}_k)^{-1} \tilde{E}_k \end{aligned} \quad (16)$$

with $\tilde{X} = (\tilde{x}_j, \tilde{X}_{(j)})$ and $\beta = (\beta_j, \beta'_{(j)})'$, where $\beta_{(j)}$ is a $(p-1) \times 1$ vector.

Diagnostics for Individual Observations

The idea discussed in the previous section can be generalized to detect outlying observations within a cluster. Let i denote the index for the individual observation that is deleted from data, and the quantity with subscript $[i]$ is evaluated by the dataset without the i th observation. Without loss of generality, X is partitioned as $X = (x_i, X_{[i]})'$, where x_i is a vector of the i th row of X ; and correspondingly,

$$B \text{ and } B^{-1} \text{ as } B = \begin{pmatrix} b_{ii} & b_{i1} \\ b_{1i} & B_{[i]} \end{pmatrix} \text{ and } B^{-1} = \begin{pmatrix} c_{ii} & c_{i1} \\ c_{1i} & C_{[i]} \end{pmatrix}.$$

Then, the first order approximation to the updating formula for $\hat{\beta}_{[i]}$ is

$$\hat{\beta}_{[i]} \approx \hat{\beta} - (\tilde{X}'\tilde{X})^{-1} \tilde{x}_i \bar{e}_i / (b_{ii}^{-1} - s_{ii}) \quad (17)$$

and the Cook's distance statistic for the i th observation on $\hat{\beta}$ has the following form

$$\begin{aligned} CD_{[i]}(\hat{\beta}) &= (\hat{\beta} - \hat{\beta}_{[i]})'(-\ddot{l}(\hat{\beta}))(\hat{\beta} - \hat{\beta}_{[i]}) / (p \cdot a^{-1}(\hat{\phi})) \\ &\approx \bar{e}_i^2 s_{ii} b_{ii}^2 / [p(1 - s_{ii} b_{ii}^2)] \end{aligned} \quad (18)$$

where $\tilde{x}_i = x_i - c_{1i} C_{[i]}^{-1} X_{[i]}$, $\bar{e}_i = e_i - c_{1i} C_{[i]}^{-1} E_{[i]}$, e_i is the i th component of the residual vector E , b_{ii} is the i th diagonal element of the matrix B and $s_{ii} = \tilde{x}_i'(\tilde{X}'\tilde{X})^{-1} \tilde{x}_i$, $i = 1, \dots, n$, $n = \sum_{j=1}^q n_j$.

Similar to the case of cluster deletion diagnostics, the Cook's distance (18) can be modified correspondingly

through the partition matrix for a subset of parameters. In particular, to assess influence of the i th individual observation on the j th component of the coefficient, the assessment $CD_{[i]}(\hat{\beta}_j)$ is then given by

$$CD_{[i]}(\hat{\beta}_j) = (\hat{\beta}_j - \hat{\beta}_{j[i]})' (-d_j' \tilde{I}^{-1}(\hat{\beta}) d_j)^{-1} (\hat{\beta}_j - \hat{\beta}_{j[i]}) / (\sigma^2(\hat{\phi})) \\ \approx \bar{e}_i^2 (s_{ii} - s_{ij})^2 / (1 - s_{ii} b_{ii})^2, \quad (19)$$

where d_j is a $p \times 1$ vector with the j th component being one and zero elsewhere, for $j = 1, \dots, p$; $s_{ii} = \bar{x}_i' (\tilde{X}' \tilde{X})^{-1} \bar{x}_i$, $\bar{x}_i = (\bar{x}_{ij}, \bar{x}_{i(j)})'$ and $s_{ij} = \bar{x}_{ij}' (\tilde{X}' \tilde{X})^{-1} \bar{x}_{i(j)}$.

In practice, a two-step detection procedure is recommended to detect outlying observations. In other words, the first step is to examine the diagnostics plot of $CD_k(\hat{\beta})$ against cluster index k to identify clusters with anomalous large influence on β . Then, the plot of $CD_{[i]}(\hat{\beta})$ against observation index i is used to identify influential observations. Results from both plots can identify whether there is any relationship between both deletion diagnostics. An example is discussed in details in the next section to illustrate the application of this detection procedure.

AN EXAMPLE

Inpatient maternity length of stay (LOS) is a readily available indicator of hospital activity. It is also considered to be a reasonable proxy of resource consumption. Obstetrical delivery is one of the most frequent causes of hospitalization in many countries. However, the appropriate LOS after delivery is a complex issue. Recent advances in medical technology and clinical practice have generally enabled obstetrical services to be provided more effectively and to improve pregnancy outcomes. In particular, streamlined delivery procedures and improved pharmaceuticals have contributed to the decline in maternity LOS.

Based on the 1998/1999 data from $N = 1,869$ women hospitalized for caesarean delivery without complicating diagnosis, the outcome variable LOS is defined to be the number of (whole) days from admission to discharge. The sample LOS observations are clustered within $q = 28$ public hospitals. In addition, concomitant information on the number of diagnoses, number of procedures, admission type (0 = elective, 1 = emergency), and payment classification (0 = public, 1 = private) are also available. In general, it is reasonable to assume that the LOS counts are independent between hospitals while certain within-hospital correlation is anticipated. Considering the histogram of responses LOS and fitted Poisson density line, data are fitted reasonably by the Poisson mixed regression model. The random effects are intended to capture discrepancies in medical expertise, obstetrical care, and other unmeasurable characteristics of the population in each hospital's catchment area. Results of which are presented in Table 1a.

First, the cluster-specified Cook's distance is considered. The exact CD_k and its first-order approximation are plotted against hospital index k in Fig. 1. The first-order approximation appears to be biased downwards compared to the exact Cook's distance. However, it clearly shows that Hospital 15 ($n_{15} = 370$) is influential on the parameter estimates. It is interesting to note that Hospital 6 ($n_6 = 111$) has the smallest average LOS among all hospitals. Results of the fit after removing Hospital 15 are summarized in Table 1b. It is noted that the patient's admission type now becomes significant, but conversely for number of procedures. After removing Hospital 15, analysis on the re-computed CD_k values based on the remaining hospitals showed that Hospital 1 is also a potential outlying hospital. This phenomenon is due to the masking effect on Hospital 1 by Hospital 15. To reinforce the indications of the diagnostics, we compare the estimation results of the Poisson linear mixed model fitted without Hospital 1 (Table 1c) and without both Hospitals 1 and 15 (Table 1d). The results clearly demonstrate the presence of masking effect in this data set.

Table 1 Parameter Estimates of the Poisson Linear Mixed Model for Maternity LOS

	(a) Full data		(b) Hospital 15 deleted		(c) Hospital 1 deleted		(d) Hospitals 1 and 15 deleted	
	$\hat{\beta}$	p -value	$\hat{\beta}$	p -value	$\hat{\beta}$	p -value	$\hat{\beta}$	p -value
Constant	1.533	0.000	1.528	0.000	1.528	0.000	1.523	0.000
No. of diagnoses	0.019	0.005	0.026	0.004	0.019	0.007	0.026	0.006
No. of procedures	0.021	0.038	0.017	0.118	0.021	0.035	0.018	0.109
Emergency admission	-0.080	0.057	-0.111	0.023	-0.049	0.254	-0.070	0.156
Private payment	0.189	0.000	0.172	0.017	0.169	0.003	0.131	0.105
$\hat{\sigma}$	0.122		0.121		0.125		0.125	

Fig. 1 Exact Cook's distance and its first-order approximation

Besides, standardized random effect predictions $\frac{\hat{u}_j}{\hat{\sigma}}$ corresponding to the four situations in Table 1 are presented in Fig. 2. Despite the substantial influence exerted by Hospitals 1 and 15 on the regression coefficients, their omissions apparently have little impact on the random effect estimates. It can be seen that Hospital numbers 6 and 15 are relatively efficient in terms of shortening the duration of hospitalization, after adjusting for the relevant risk factors. Incidentally, Hospital number 15 corresponds to a large teaching hospital while Hospital 1 is a small rural hospital with $n_1 = 62$. Hospital 6 is a regional maternity hospital that reported the shortest average LOS of 3.7 days and none of its $n_6 = 111$ patients have private insurance cover. These findings have important implications in terms of hospital resource allocation and efficiency assessment. Regarding the influence of each hospital on each regression coefficient, Fig. 3 shows that only Hospital 15 is influential.

Finally, regarding the issue of detecting outlying observations, the diagnostic plot of $CD_{[i]}$ versus individual index

Fig. 2 Estimated hospital effects from fitting Poisson linear mixed model

Fig. 3 Approximate Cook's distance for each regression coefficient

i is given in Fig. 4. It can be found that the observation of patient No. 1777 has the greatest $CD_{[i]}$, which is obviously much greater than the second largest one. In fact, the LOS of this patient is 14 days, which is the second largest response value. However, this individual patient is from the twenty-third hospital, which is not detected to be an influential cluster according to the previous analysis. It indicates that this influential individual does not cause the hospital where he or she stayed to be influential. On the other hand, no individual observations from influential cluster 15 or cluster 1 show obvious evidence of individual influence on the estimate of the parameter. In particular, after deleting the individual 1777 from the complete dataset, the estimates of β and σ are $\hat{\beta} = (1.5324, 0.0196, 0.0205, -0.0926, 0.1664)'$ and $\hat{\sigma} = 0.1221$ respectively, which are not much different from parameter estimates based on the full data as shown in Table 1a. Hence, only regarding the magnitude of the estimate may not identify the anomalous individual observation out of a large data set.

Fig. 4 First order approximate Cook's distance for individual observations

One final remark before concluding this section is on the assessment of the Cook's values: There has been much debate about how these values should be used. Some suggested comparing these to an absolute cutoff value based on some approximate distribution of the Cook's distance statistic. For example, in the linear regression case, values of CD_k and $CD_{[i]}$ can be approximately evaluated with reference to the χ^2_{p-1} distribution to some extent as pointed out by Cook and Weisberg.^[3] However, this criterion is always overly conservative in practice. The situation is anticipated to be much more unclear in GLMM because of its complicated model structure. Alternatively, it would be more effective to identify those clusters or observations with unusually large CD values; and compare the fitting results with and without the identified observations.

CONCLUSION

All the techniques discussed above are focused on the detection of a single outlying observation or cluster based on the assumption that the proposed model is valid. The problem of identifying a single outlying observation or cluster is relatively simple from both analytical and computational points of view. If the data set contains more than one outlying observation or cluster, which is not unlikely for many data sets, it would be much more difficult to identify these outliers due to the masking and swamping effects. The former is concerned with the impact of a particular observation that may not be apparent until another observation has been deleted. The latter refers to observations that are jointly but not individually influential. In fact, these effects are presented in the LOS data set discussed in section "An Example". The masking effects of deletion diagnostics may be considered in terms of joint influence and conditional influence. Hadi and Simonoff^[14] consider the problem of identifying and testing multiple outliers in linear models.^[14] Generalized cluster-wise joint and conditional deletion measures can be developed for investigating effects of masking in GLMM setting similar to the approach suggested by Lawrance.^[15]

The objective of detecting outliers from a clinical study is to improve the validity of the statistical procedure and draw proper conclusions. After some data are identified as potential outliers in a data set by appropriate statistical techniques, statisticians are often faced with the dilemma

in how to deal with these outliers. However, there is not any standard answer to the question of whether or not to include the data. Experimenters should review the process critically to identify a cause for these outlying observations. If they are caused by errors committed in the research process, then the data can be discarded from the study without inducing any bias to the conclusion. In general, the decision to discard any outlier(s) from the study should be made cautiously. It should be done only after thorough review of the properties of the data and the insight of the experimenter.

Clinical Research: Reproducibility Probability

Shein-Chung Chow

Duke University School of Medicine, Durham, North Carolina, U.S.A.

Abstract

This entry reviews three approaches to reproducibility probability and provides examples and applications for this clinical research tool.

INTRODUCTION

For marketing approval of a new drug product, the United States Food and Drug Administration (FDA) requires that at least two adequate and well-controlled clinical trials be conducted to provide substantial evidence regarding the effectiveness and safety of the drug product under investigation.^[1] Under certain circumstances, however, the FDA Modernization Act (FDAMA) of 1997 includes a provision (Section 115 of FDAMA) to allow data from one adequate and well-controlled clinical trial investigation and confirmatory evidence to establish effectiveness for risk/benefit assessment of drug and biological candidates for approval. The purpose of requiring at least two clinical studies is to assure that clinical results are reproducible. *Reproducibility*, in clinical research, is then referred to as whether the clinical results are reproducible from a location (e.g., a study site or center) to another location within the same region (e.g., the United States, Europe, or Asian Pacific Region) or from region to region with respect to the same patient population.

In practice, it is often of interest to determine whether a clinical trial that produced positive clinical results provides substantial evidence to assure reproducibility of the clinical results. In this entry, the reproducibility of a positive clinical result is studied by evaluating the probability of observing a positive result in a future clinical study with the same study protocol, given that a positive clinical result has been observed.

In the section “Reproducibility Probability,” the concept of reproducibility probability of a positive clinical result is introduced. Three different approaches of evaluating the reproducibility probability, namely, the estimated power approach, the confidence bound approach, and the Bayesian approach, are discussed in the sections “The Estimated Power Approach” and “The Confidence Bound Approach,” respectively. Applications and extensions of the derived results are discussed in the section “The Bayesian Approach.” For example, if the reproducibility probability is high (e.g., 95%) with some statistical assurance based on the results from the first clinical trial, then it may not be necessary to require the sponsor to conduct the second clinical trial.

REPRODUCIBILITY PROBABILITY

Let H_0 be the null hypothesis that the mean response of the drug product is the same as the mean response of a control (e.g., placebo). When H_0 is concluded, the drug product is not considered to be effective. Let T be the test statistic based on the responses from a clinical trial. The clinical trial produces a positive clinical result if the observed value of T leads to the rejection of the null hypothesis H_0 .

Let H_1 be the alternative hypothesis which states that H_0 is not true. Suppose that the null hypothesis H_0 is rejected if and only if $|T| > c$, where c is a positive known constant. This is usually related to a two-sided alternative hypothesis. The discussion for one-sided alternative hypotheses is similar. In statistical theory, the probability of observing a positive clinical result when H_1 is indeed true, which is commonly denoted by

$$P(|T| > c | H_1) \quad (1)$$

is referred to as the power of the test procedure. Typically, the power is a function of unknown parameters.

Consider two independent clinical trials of the same study protocol and sample size. The power for each trial is given by Eq. 1, whereas the probability that *both* trials yield positive results when H_1 is true is

$$[P(|T| > c | H_1)]^2$$

because the two trials are independent. For example, if the power for a single study is 80%, then the probability of observing two positive clinical results when H_1 is true is $(80\%)^2 = 64\%$.

Suppose now that one clinical trial was conducted and the result is positive. What is the probability that the second trial will produce a positive result, i.e., the positive result from the first trial is reproducible? Mathematically, because the two trials are independent, the probability of observing a positive result in the second trial when H_1 is true is still given by Eq. 1, regardless of whether the result from the first trial is positive or not. However, information from the first

clinical trial should be useful in the evaluation of the probability of observing a positive result in the second trial. This leads to the concept of reproducibility probability, which is different from the power defined by Eq. 1.

In general, the reproducibility probability is a person's subjective probability of observing a positive clinical result from the second trial, when he/she observes a positive result from the first trial. For example, the reproducibility probability can be defined as the probability in Eq. 1 with all unknown parameters replaced by their estimates from the first trial.^[2] In other words, the reproducibility probability is defined to be an estimated power of the second trial using the data from the first trial. More discussions of this approach will be given in the subsequent sections.

Perhaps a more sensible definition of reproducibility probability can be obtained by using the Bayesian approach.^[3] Under the Bayesian approach, the unknown parameter under H_1 , denoted by θ is a random vector with a prior distribution $\pi(\theta)$ assumed to be known. Thus

$$P(|T| > c | H_1) = P(|T| > c | \theta)$$

and the reproducibility probability can be defined as the conditional probability of $|T| > c$ in the second trial, given the data set x observed from the first trial, i.e.,

$$P(|T| > c | x) = \int P(|T| > c | \theta) \pi(\theta | x) d\theta \quad (2)$$

where $T = T(y)$ is based on the data set y from the second trial and $\pi(\theta | x)$ is the posterior density of θ , given x .

THE ESTIMATED POWER APPROACH

To study the reproducibility probability, we need to specify the test procedure, i.e., the form of the test statistic T . We first consider the simplest design of two parallel groups with equal variances. The case of unequal variances is considered next. The parallel-group design is discussed at the end of this section.

Two Samples with Equal Variances

Suppose that a total of $n = n_1 + n_2$ patients are randomly assigned to two groups, a treatment group and a control group. In the treatment group, n_1 patients receive the treatment (or a test drug) and produce responses $x_{11}, \dots, x_{1n_1}$. In the control group, n_2 patients receive the placebo (or a reference drug) and produce responses $x_{21}, \dots, x_{2n_2}$. This design is a typical two-group parallel design in clinical trials. We assume that x_{ij} 's are independent and normally distributed with means $\mu_i, i = 1, 2$, and a common variance σ^2 . Suppose that the hypotheses of interest are

$$H_0: \mu_1 - \mu_2 = 0 \quad \text{vs.} \quad H_1: \mu_1 - \mu_2 \neq 0 \quad (3)$$

The discussion for a one-sided H_1 is similar.

When σ^2 is known, we reject H_0 at the 5% level of significance if and only if

$$|T| > z_{0.975} \quad (4)$$

where $z_{0.975}$ is the 97.5th percentile of the standard normal distribution,

$$T = \frac{\bar{x}_1 - \bar{x}_2}{\sigma \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \quad (5)$$

and $\bar{x}_i$ is the sample mean based on the data in the i th group.

Consider two independent clinical trials of the same design. Let x denote the data observed from the first trial and y be the data to be observed from the second trial. The test statistics for two trials are denoted by $T(x)$ and $T(y)$, respectively. For T given by Eq. 5, the power of T for the second trial is

$$P(|T(y)| > z_{0.975}) = \Phi(\theta - z_{0.975}) + \Phi(-\theta - z_{0.975}) \quad (6)$$

where Φ is the standard normal distribution function and

$$\theta = \frac{\mu_1 - \mu_2}{\sigma \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \quad (7)$$

If we replace θ in Eq. 6 by its estimate based on the data from the first trial, $T(x)$, then an estimated power, which can be defined as the reproducibility probability, is given by

$$\hat{P} = \Phi(T(x) - z_{0.975}) + \Phi(-T(x) - z_{0.975}) \quad (8)$$

Note that $\hat{P}$ is a function of $|T(x)|$. When $|T(x)| > z_{0.975}$ (i.e., the first trial yields a positive clinical result),

$$\hat{P} \approx \Phi(|T(x)| - z_{0.975})$$

which is the formula for reproducibility probability given by Goodman.^[2] Values of in Eq. 8 for several different values of $|T(x)|$ (and the related p -values) are listed in the third column of Table 1. As can be seen in Table 1, if the P -value observed from the first trial is less than 0.001, there is more than 90% chance that the clinical result will be reproducible in the second trial under the same protocol and clinical trial environments.

In practice, σ^2 is usually unknown and, thus, the test given by Eqs. 4 and 5 needs to be replaced by the commonly used two sample t -test which rejects H_0 if and only if

$$|T| > t_{0.975; n-2}$$

Table 1 Reproducibility Probability $\hat{P}$

$ T(x) $	Known σ^2		Unknown σ^2 ($n = 30$)	
	p-Value	$\hat{P}$	p-Value	$\hat{P}$
1.96	0.050	0.500	0.060	0.473
2.05	0.040	0.536	0.050	0.508
2.17	0.030	0.583	0.039	0.554
2.33	0.020	0.644	0.027	0.614
2.58	0.010	0.732	0.015	0.702
2.81	0.005	0.802	0.009	0.774
3.30	0.001	0.910	0.003	0.890

where $t_{0.975;n-2}$ is the 97.5th percentile of the t-distribution with $n - 2$ degrees of freedom,

$$T = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n - 2}} \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \quad (9)$$

and s_i^2 is the sample variance based on the data from the i th group. Then the power of T for the second trial is

$$p(\theta) = P(|T(y)| > t_{0.975;n-2}) \\ = 1 - T_{n-2}(t_{0.975;n-2}|\theta) + T_{n-2}(-t_{0.975;n-2}|\theta) \quad (10)$$

where θ is given by Eq. 7 and $T_{n-2}(\cdot|\theta)$ denotes the distribution function of the noncentral t-distribution with $n - 2$ degrees of freedom and the noncentrality parameter θ . Note that $p(\theta) = p(|\theta|)$. Values of $p(\theta)$ as a function of $|\theta|$ is provided in Table 2. Using the same idea of replacing θ by its estimate $T(x)$, where T is now defined by Eq. 9, we obtain the following reproducibility probability:

$$\hat{p} = 1 - T_{n-2}(t_{0.975;n-2}|T(x)) + T_{n-2}(-t_{0.975;n-2}|T(x)) \quad (11)$$

which is a function of $|T(x)|$. Again, when $|T(x)| > t_{0.975;n-2}$,

$$\hat{P} \approx \begin{cases} 1 - T_{n-2}(t_{0.975;n-2}|T(x)) & \text{if } T(x) > 0 \\ T_{n-2}(-t_{0.975;n-2}|T(x)) & \text{if } T(x) < 0 \end{cases}$$

For comparison, values of $\hat{P}$ in Eq. 11 for $n = 30$ corresponding to $\hat{P}$ in Eq. 8 are listed in the fifth column of Table 1. It can be seen that with the same value of $T(x)$, the reproducibility probability for the case of unknown σ^2 is lower than that for the case of known σ^2 .

Table 2 can be used to find the reproducibility probability $\hat{P}$ in Eq. 11 with a fixed sample size n . For example, if $T(x) = 2.9$ was observed in a clinical trial with $n = n_1 + n_2 = 40$, then the reproducibility probability is 0.807. If $|T(x)| = 2.9$ was observed in a clinical trial with $n = 36$, then an extrapolation of the results in Table 2 (for $n = 30$ and 40) leads to a reproducibility probability of 0.803.

Two Samples with Unequal Variances

Consider the problem of testing hypotheses (Eq. 3) under the two-group parallel design without the assumption of equal variances. That is, x_{ij} 's are independently distributed as $N(\mu_i, \sigma_i^2)$, $i = 1, 2$.

When $\sigma_1^2 \neq \sigma_2^2$, there exists no exact testing procedure for the hypotheses in Eq. 3. When both n_1 and n_2 are large, an approximate 5% level test rejects H_0 when $|T| > z_{0.975}$, where

$$T = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}} \quad (12)$$

Because T is approximately distributed as $N(\theta, 1)$ with

$$\theta = \frac{\mu_1 - \mu_2}{\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}} \quad (13)$$

the reproducibility probability obtained by using the estimated power approach is given by Eq. 8 with T defined by Eq. 12.

When the variances under different treatments are different and the sample sizes are not large, a different study design, such as a matched-pair parallel design or a 2×2 crossover design is recommended. A matched-pair parallel design involves m pairs of matched patients. One patient in each pair is assigned to the treatment group and the other is assigned to the control group. Let x_{ij} be the observation from the j th pair and the i th group. It is assumed that the differences $x_{1j} - x_{2j}$, $j = 1, \dots, m$, are independent and identically distributed as $N(\mu_1 - \mu_2, \sigma_D^2)$. Then, the null hypothesis H_0 is rejected at the 5% level of significance if $|T| > t_{0.975;m-1}$, where

$$T = \frac{\sqrt{m}(\bar{x}_1 - \bar{x}_2)}{\hat{\sigma}_D} \quad (14)$$

and $\hat{\sigma}_D^2$ is the sample variance based on the differences $x_{1j} - x_{2j}$, $j = 1, \dots, m$. Note that T has the noncentral t -distribution with $n - 1$ degrees of freedom and the noncentrality parameter

$$\theta = \frac{\sqrt{m}(\mu_1 - \mu_2)}{\sigma_D} \quad (15)$$

Consequently, the reproducibility probability obtained by using the estimated power approach is given by Eq. 11 with T defined by Eq. 16 and $n - 2$ replaced by $m - 1$.

Suppose that the study design is a 2×2 crossover design in which n_1 patients receive the treatment at the first period and the placebo at the second period and n_2 patients

receive the placebo at the first period and the treatment at the second period. Let x_{ij} be the normally distributed observation from the j th patient at the i th period and l th sequence. Then the treatment effect μ_D can be unbiasedly estimated by

$$\hat{\mu}_D = \frac{\bar{x}_{11} - \bar{x}_{12} - \bar{x}_{21} + \bar{x}_{22}}{2} \sim N\left(\mu_D, \frac{\sigma_{1,1}^2}{4} \left(\frac{1}{n_1} + \frac{1}{n_2}\right)\right)$$

where $\bar{x}_{ij}$ is the sample mean based on x_{ij} , $j = 1, \dots, n_i$, and $\sigma_{1,1}^2$ is a function of variance components, where $\sigma_{1,1}^2 = \sigma_D^2 + \sigma_{WT}^2 + \sigma_{WR}^2$ in which σ_{WT}^2 and σ_{WR}^2 are intrasubject variances for the test product and the reference product, respectively. An unbiased estimator of $\sigma_{1,1}^2$ is

$$\hat{\sigma}_{1,1}^2 = \frac{1}{n_1 + n_2 - 2} \sum_{i=1}^2 \sum_{j=1}^{n_j} (x_{i1j} - x_{i2j} - \bar{x}_{i1} + \bar{x}_{i2})^2$$

which is independent of $\hat{\mu}_D$ and distributed as $\sigma_{1,1}^2 / (n_1 + n_2 - 2)$ times the χ^2 distribution with $n_1 + n_2 - 2$ degrees of freedom. Thus the null hypothesis $H_0: \mu_D = 0$ is rejected at the 5% level of significance if $|T| > t_{0.975, n-2}$, where $n = n_1 + n_2$ and

$$T = \frac{\hat{\mu}_D}{\frac{\hat{\sigma}_{1,1}}{2} \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \quad (16)$$

Note that T has the noncentral t -distribution with $n - 2$ degrees of freedom and the noncentrality parameter

$$\theta = \frac{\mu_D}{\frac{\sigma_{1,1}}{2} \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \quad (17)$$

Consequently, the reproducibility probability obtained by using the estimated power approach is given by Eq. 11 with T defined by Eq. 16.

Parallel-Group Designs

Parallel-group designs are often employed in clinical trials to compare more than one treatment with a placebo control or to compare one treatment, one placebo control, and one active control. Let $a \geq 3$ be the number of groups and x_{ij} be the observation from the j th patient in the i th group, $j = 1, \dots, n_i$, $i = 1, \dots, a$. Assume that x_{ij} 's are independently distributed as $N(\mu_i, \sigma^2)$. The null hypothesis H_0 is then

$$H_0: \mu_1 = \mu_2 = \dots = \mu_a$$

which is rejected at the 5% level of significance if $T > F_{0.95; a-1, n-a}$, where $F_{0.95; a-1, n-a}$ is the 95th percentile of the F -distribution with $a-1$ and $n-a$ degrees of freedom, $n = n_1 + \dots + n_a$,

$$T = \frac{SST/(a-1)}{SSE/(n-a)}, \quad SST = \sum_{i=1}^a n_i (\bar{x}_i - \bar{x})^2, \quad (18)$$

$$= SSE = \sum_{i=1}^a \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_i)^2$$

$\bar{x}_i$ is the sample mean based on the data in the i th group, and is the overall sample mean.

Note that T has the noncentral F -distribution with $a-1$ and $n-a$ degrees of freedom and the noncentrality parameter

$$\theta = \sum_{i=1}^a \frac{n_i (\mu_i - \bar{\mu})^2}{\sigma^2} \quad (19)$$

where $\bar{\mu} = \sum_{i=1}^a n_i \mu_i / n$. Let $F_{a-1, n-a}(\cdot | \theta)$ be the distribution function of T . Then, the power of the second clinical trial is

$$P(T(y) > F_{0.95; a-1, n-a}) = 1 - F_{a-1, n-a}(F_{0.95; a-1, n-a} | \theta)$$

Thus the reproducibility probability obtained by using the estimated power approach is

$$\hat{P} = 1 - F_{a-1, n-a}(F_{0.95; a-1, n-a} | T(x))$$

where $T(x)$ is the observed T based on the data x from the first clinical trial.

THE CONFIDENCE BOUND APPROACH

Because $\hat{P}$ in Eq. 8 or Eq. 11 is an estimated power, it provides a rather optimistic result. Alternatively, we may consider a more conservative approach, which considers a 95% lower confidence bound of the power as the reproducibility probability.^[3]

Consider first the case of the two-group parallel design with a known common variance σ^2 . Note that a 95% lower confidence bound for $|\theta|$, where θ is given by Eq. 7, is

$$|T(x)| - z_{0.975}$$

where T is given by Eq. 5. Because

$$P(|T(y)| > z_{0.975}) \geq \Phi(|\theta| - z_{0.975})$$

and Φ is a strictly increasing function, a 95% lower confidence bound for the power is

$$\hat{P}_- = \Phi(|T(x)| - 2z_{0.975}) \quad (20)$$

Note that the lower confidence bound in Eq. 20 is not useful unless $|T(x)| \geq 2z_{0.975}$, i.e., the positive clinical result from the first trial is highly significant.

When σ^2 is unknown, it is more difficult to obtain a confidence bound for θ in Eq. 7. Note that $T(x)$ defined by Eq. 9 has the noncentral t -distribution with $n-2$ degrees of freedom and the noncentrality parameter θ . Let $\mathcal{T}_{n-2}(\cdot | \theta)$ be the distribution function of $T(x)$ for any given θ . It can be shown that $\mathcal{T}_{n-2}(t | \theta)$ is a strictly decreasing function of θ for any fixed t . Consequently, a 95% confidence interval for θ is $(\hat{\theta}_-, \hat{\theta}_+)$, where $\hat{\theta}_\pm$ is the unique solution of

$$\mathcal{T}_{n-2}(T(x) | \theta) = 0.975$$

and $\hat{\theta}_+$ is the unique solution of

$$\mathcal{T}_{n-2}(T(x) | \theta) = 0.025$$

(see, e.g., Theorem 7.1 in Ref. [4]). Then, a 95% lower confidence bound for $|\theta|$ is

$$|\hat{\theta}|_- = \begin{cases} \hat{\theta}_- & \text{if } \hat{\theta}_- > 0 \\ -\hat{\theta}_+ & \text{if } \hat{\theta}_+ < 0 \\ 0 & \text{if } \hat{\theta}_- \leq 0 \leq \hat{\theta}_+ \end{cases} \quad (21)$$

and a 95% lower confidence bound for the power $p(\theta)$ in Eq. 10 is

$$\hat{P}_- = 1 - \mathcal{T}_{n-2}(t_{0.975; n-2} | |\hat{\theta}|_-) + \mathcal{T}_{n-2}(-t_{0.975; n-2} | |\hat{\theta}|_-) \quad (22)$$

if $|\hat{\theta}|_- > 0$ and $\hat{P}_- = 0$ if $|\hat{\theta}|_- = 0$. Again, the lower confidence bound in Eq. 22 is useful when the clinical result from the first trial is highly significant.

Table 3 contains values of the lower confidence bound $|\hat{\theta}|_-$ corresponding to $|T(x)|$ values ranging from 4.0 to 6.5. If $4 \leq |T(x)| \leq 6.5$ and the value of $|\hat{\theta}|_-$ is found in Table 3, the reproducibility probability $\hat{P}_-$ in Eq. 22 can be obtained in Table 2. For example, suppose that $|T(x)| = 5$ was observed from a clinical trial with $n = 30$. From Table 3, $|\hat{\theta}|_- = 2.6$. Then, by Table 2, $\hat{P}_- = 0.709$.

While $\hat{P}$ in Eq. 11 is rather optimistic, $\hat{P}_-$ in Eq. 22 may be too conservative. One compromise is to reduce the significance level of the lower confidence bound $|\hat{\theta}|_-$ to 90%. Table 4 contains values of the 90% lower confidence bound for $|\theta|$. For $n = 30$ and $|T(x)| = 5$, $|\hat{\theta}|_-$ is 2.98, which leads to $\hat{P}_- = 0.82$.

Consider next the two-group parallel design with unequal variances σ_1^2 and σ_2^2 . When both n_1 and n_2 are large, T given by Eq. 12 is approximately distributed as $N(\theta, 1)$ with θ given by Eq. 13. Hence the reproducibility probability obtained by using the lower confidence bound approach is given by Eq. 20 with T defined by Eq. 12.

Table 3 95% Lower Confidence Bound $|\hat{\theta}|$

6.5	2.75	3.57	3.86	4.02	4.12	4.18	4.32	4.54

For the matched-pair parallel design described above, T given by Eq. 14 has the noncentral t -distribution with $m - 1$ degrees of freedom and the noncentrality parameter θ given by Eq. 15. Hence the reproducibility probability obtained by using the lower confidence bound approach is given by Eq. 22 with T defined by Eq. 14 and $n - 2$ replaced by $m - 1$.

Suppose now that the study design is the 2×2 crossover design. Because T defined by Eq. 16 has the noncentral t -distribution with $n - 2$ degrees of freedom and the noncentrality parameter θ given by Eq. 17, the reproducibility probability obtained by using the lower confidence bound approach is given by Eq. 22 with T defined by Eq. 16.

Finally, consider the parallel-group design described above. Because T in Eq. 18 has the noncentral F -distribution with $a - 1$ and $n - a$ degrees of freedom and the noncentrality parameter θ given by Eq. 19 and $F_{a-1, n-a}(t | \theta)$ is a strictly decreasing function of θ , the reproducibility probability obtained by using the lower confidence bound approach is

$$\hat{P}_- = 1 - F_{a-1, n-a}(F_{0.95; a-1, n-a} | \hat{\theta}_-)$$

where $\hat{\theta}_-$ is the solution of

$$F_{a-1, n-a}(T(x) | \theta) = 0.95$$

THE BAYESIAN APPROACH

As discussed earlier, the reproducibility probability can be viewed as the posterior mean of the power function $p(\theta) = P(|T| > c | \theta)$ for the second trial. Thus under the Bayesian approach, it is essential to construct the posterior density $\pi(\theta | x)$ in formula 2, given the dataset x observed from the first trial.^[3]

Two Samples with Equal Variances

Consider the two-group parallel design described above with equal variances, i.e., x_{ij} 's are independent and normally distributed with means μ_1 and μ_2 and a common variance σ^2 .

If σ^2 is known, then the power for testing hypotheses in Eq. 3 is given by Eq. 6 with θ defined by Eq. 7. A commonly used prior for (μ_1, μ_2) is the noninformative prior $\pi(\mu_1, \mu_2) \equiv 1$. Consequently, the posterior density for θ is $N(T(x), 1)$, where T is given by Eq. 5, and the posterior mean given by Eq. 2 is

$$\begin{aligned} & \int [\Phi(\theta - z_{0.975}) + \Phi(-\theta - z_{0.975})] \pi(\theta | x) d\theta \\ &= \Phi\left(\frac{T(x) - z_{0.975}}{\sqrt{2}}\right) + \Phi\left(\frac{-T(x) - z_{0.975}}{\sqrt{2}}\right) \end{aligned}$$

Table 4 90% Lower Confidence Bound $|\hat{\theta}|_L$

$ T(x) $	N							
	10	20	30	40	50	60	100	∞
4.5	1.95	2.40	2.54	2.62	2.67	2.70	2.76	2.86
4.6	2.02	2.48	2.63	2.71	2.76	2.79	2.85	2.96

5.3	2.49	3.05	3.24	3.34	3.40	3.44	3.52	3.66
5.4	2.56	3.13	3.33	3.43	3.49	3.54	3.62	3.76
5.5	2.63	3.21	3.42	3.52	3.59	3.63	3.72	3.86
5.6	2.69	3.30	3.50	3.61	3.68	3.72	3.81	3.96
5.7	2.76	3.38	3.59	3.70	3.77	3.81	3.91	4.06
5.8	2.83	3.46	3.68	3.79	3.86	3.91	4.00	4.16
5.9	2.89	3.54	3.76	3.88	3.95	3.00	4.10	4.26
6.0	2.96	3.62	3.85	3.97	4.04	4.09	4.19	4.36
6.1	3.02	3.70	3.93	4.06	4.13	4.18	4.29	4.46
6.2	3.09	3.78	4.02	4.15	4.22	4.28	4.38	4.56
6.3	3.15	3.86	4.11	4.23	4.31	4.37	4.48	4.66
6.4	3.22	3.94	4.19	4.32	4.40	4.46	4.57	4.76
6.5	3.28	4.02	4.28	4.41	4.49	4.55	4.67	4.86

When $|T(x)| > z_{0.975}$, this probability is nearby the same as

$$\Phi\left(\frac{|T(x)| - z_{0.975}}{\sqrt{2}}\right) \quad (23)$$

which is exactly the same as that in formula 1 in Goodman.^[2]

For the more realistic situation where σ^2 is unknown, we need a prior for σ^2 . A commonly used noninformative prior for σ^2 is the Lebesgue (improper) density $\pi(\sigma^2) = \sigma^{-2}$. Assume that the priors for μ_1 , μ_2 , and σ^2 are independent. The posterior density for (δ, u^2) is

$$\pi(\delta|u^2, x)\pi(u^2|x)$$

where

$$\delta = \frac{\mu_1 - \mu_2}{\sqrt{\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n - 2} \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}},$$

$$u^2 = \frac{(n - 2)\sigma^2}{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}, \quad \pi(\delta|u^2, x) = \frac{1}{u} \phi\left(\frac{\delta - T(x)}{u}\right)$$

ϕ is the density function of the standard normal distribution, T is given by Eq. 9, and $\pi(u^2|x) = f(u)$ with

$$f(u) = \left[\Gamma\left(\frac{n-2}{2}\right) \right]^{-1} \left(\frac{n-2}{2}\right)^{(n-2)/2} u^{-n} e^{-(n-2)/(2u^2)}$$

Because θ in Eq. 7 is equal to δ/u , the posterior mean of $p(\theta)$ in Eq. 10 is

$$\hat{P} = \int_0^\infty \left[\int_{-\infty}^\infty p\left(\frac{\delta}{u}\right) \phi\left(\frac{\delta - T(x)}{u}\right) d\delta \right] 2f(u) du \quad (24)$$

which is the reproducibility probability under the Bayesian approach. It is clear that depends on the data x through the function $T(x)$.

The probability $\hat{P}$ in Eq. 24 can be evaluated numerically. A Monte Carlo method can be applied as follows. First, generate a random variate γ_j from the gamma distribution with the shape parameter $(n-2)/2$ and the scale parameter $2/(n-2)$, and generate a random variate δ_j from $N(T(x), u_j^2)$, where $u_j^2 = \gamma_j^{-1}$. Repeat this process independently N times to obtain (δ_j, u_j^2) , $j = 1, \dots, N$. Then in Eq. 24 can be approximated by

$$\hat{P}_N = 1 - \frac{1}{N} \sum_{j=1}^N \left[T_{n-2} \left(t_{0.975; n-2} \left| \frac{\delta_j}{u_j} \right| \right) - T_{n-2} \left(-t_{0.975; n-2} \left| \frac{\delta_j}{u_j} \right| \right) \right] \quad (25)$$

Values of $\hat{P}_N$ for $N = 10,000$ and some selected values of $T(x)$ and n are given by Table 5. It can be seen that in assessing reproducibility, the Bayesian approach is more conservative than the estimated power approach, but less conservative than the confidence bound approach.

Two Samples with Unequal Variances

Consider first the two-group parallel design with unequal variance and large n_i 's. The approximate power for the second trial is

$$p(\theta) = \Phi(\theta - z_{0.975}) + \Phi(-\theta - z_{0.975}),$$

$$\theta = \frac{\mu_1 - \mu_2}{\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}}$$

Suppose that we use the following noninformative prior density for $(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2)$:

$$\pi(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2) = \sigma_1^{-2} \sigma_2^{-2}, \quad \sigma_1^2 > 0, \sigma_2^2 > 0$$

Let $\tau_i^2 = \sigma_i^{-2}, i = 1, 2$, and $\zeta^2 = 1/n_1 \tau_1^2 + 1/n_2 \tau_2^2$. Then, the posterior density $\pi(\mu_1 - \mu_2 | \tau_1^2, \tau_2^2, x)$ is the normal density with mean $1 - 2$ and variance ζ^2 and the posterior density

$$\pi(\tau_1^2, \tau_2^2 | x) = \pi(\tau_1^2 | x) \pi(\tau_2^2 | x)$$

where $\pi(\tau_i^2 | x)$ is the gamma density with the shape parameter $(n_i - 1)/2$ and the scale parameter $2/[(n_i - 1) s_i^2], i = 1, 2$. Consequently, the posterior mean of $p(\theta)$ is

$$\begin{aligned} & \iiint \Phi(\theta - z_{0.975}) \pi(\mu_1 - \mu_2 | \tau_1^2, \tau_2^2, x) d(\mu_1 - \mu_2) \\ & \times \pi(\tau_1^2, \tau_2^2 | x) d\tau_1^2 d\tau_2^2 + \iiint \Phi(-\theta - z_{0.975}) \\ & \times \pi(\mu_1 - \mu_2 | \tau_1^2, \tau_2^2, x) d(\mu_1 - \mu_2) \pi(\tau_1^2, \tau_2^2 | x) d\tau_1^2 d\tau_2^2 \end{aligned}$$

Note that

$$\begin{aligned} & \int \Phi(\theta - z_{0.975}) \pi(\mu_1 - \mu_2 | \tau_1^2, \tau_2^2, x) d(\mu_1, \mu_2) \\ & = \Phi\left(\frac{\bar{x}_1 - \bar{x}_2}{\sqrt{2}\zeta} - \frac{z_{0.975}}{\sqrt{2}}\right) \end{aligned}$$

and

$$\begin{aligned} & \int \Phi(-\theta - z_{0.975}) \pi(\mu_1 - \mu_2 | \tau_1^2, \tau_2^2, x) d(\mu_1, \mu_2) \\ & = \Phi\left(-\frac{\bar{x}_1 - \bar{x}_2}{\sqrt{2}\zeta} - \frac{z_{0.975}}{\sqrt{2}}\right) \end{aligned}$$

Hence the reproducibility probability based on the Bayesian approach is

$$\hat{P} = \int \left[\Phi\left(\frac{\bar{x}_1 - \bar{x}_2}{\sqrt{2}\zeta} - \frac{z_{0.975}}{\sqrt{2}}\right) + \Phi\left(-\frac{\bar{x}_1 - \bar{x}_2}{\sqrt{2}\zeta} - \frac{z_{0.975}}{\sqrt{2}}\right) \right] \times \pi(\zeta | x) d\zeta$$

where $\pi(\zeta | x)$ is the posterior density of ζ constructed using $\pi(\tau_i^2 | x), i = 1, 2$.

The following Monte Carlo method can be applied to evaluate. Generate independent random variates τ_{1j}^2 and τ_{2j}^2 , respectively, from the gamma densities $\pi(\tau_1^2 | x)$ and $\pi(\tau_2^2 | x)$ as previously specified. Repeat this process independently N times to obtain $(\tau_{1j}^2, \tau_{2j}^2), j = 1, \dots, N$. Then $\hat{P}$ can be approximated by

$$\hat{P}_N = \frac{1}{N} \sum_{j=1}^N \left[\Phi\left(\frac{\bar{x}_1 - \bar{x}_2}{\sqrt{2}\zeta_j} - \frac{z_{0.975}}{\sqrt{2}}\right) + \Phi\left(-\frac{\bar{x}_1 - \bar{x}_2}{\sqrt{2}\zeta_j} - \frac{z_{0.975}}{\sqrt{2}}\right) \right]$$

where

$$\zeta_j = \frac{1}{n_1 \tau_{1j}^2} + \frac{1}{n_2 \tau_{2j}^2}, \quad j = 1, \dots, N$$

For the matched-pairs parallel design, the power function is

$$p(\theta) = 1 - T_{m-1}(t_{0.975; m-1} | \theta) + T_{m-1}(-t_{0.975; m-1} | \theta)$$

with θ given by Eq. 15. Under the noninformative prior $\pi(\mu, \sigma_D^2) = \sigma_D^{-1}$, the reproducibility probability, the posterior mean of $p(\theta)$, is given by Eq. 24 with T given by Eq. 14, $n - 2$ replaced by $m - 1$, and δ and u^2 defined by

$$\delta = \frac{\sqrt{n}(\mu_1 - \mu_2)}{\sigma_D} \quad \text{and} \quad \mu^2 = \frac{\sigma_D^2}{\hat{\sigma}_D^2}$$

respectively.

For the 2×2 crossover design, the power function is $p(\theta) = 1 - T_{n-2}(t_{0.975; n-2} | \theta) + T_{n-2}(-t_{0.975; n-2} | \theta)$ with θ given by Eq. 17. If we use the noninformative prior $\pi(\mu, \sigma_{1,1}^2) = \sigma_{1,1}^{-1}$, then the reproducibility probability is still given by Eq. 24 with T given by Eq. 16, δ and u^2 defined by

Table 5 Reproducibility Probability $\hat{P}_N$ Given by Eq. 25

respectively.

Parallel-Group Designs

Consider the a -group parallel design, where the power is given by

$$p(\theta) = 1 - F_{a-1, n-a}(F_{0.95; a-1, n-a} | \theta)$$

with θ given by Eq. 19. Under the noninformative prior

$$\pi(\mu_1, \dots, \mu_a, \sigma^2) = \sigma^{-2}, \sigma^2 > 0$$

the posterior density $\pi(\theta | \tau^2, x)$, where $\tau^2 = \text{SSE} / [(n - a)\sigma^2]$, is the density of the noncentral χ^2 distribution with $a - 1$ degrees of freedom and the noncentrality parameter $\tau^2(a - 1)T(x)$. The posterior density $\pi(\tau^2 | x)$ is the gamma

distribution with the shape parameter $(n - a)/2$ and the scale parameter $2/(n - a)$. Consequently, the reproducibility probability under the Bayesian approach is

$$\hat{P} = \int_0^\infty \left[\int_{-\infty}^\infty p(\theta) \pi(\theta | \tau^2, x) d\theta \right] \pi(\tau^2 | x) d\tau^2$$

A similar Monte Carlo method can be applied to compute $\hat{P}$.

APPLICATION AND EXTENSIONS

In this section, we discuss some applications and extensions of the results obtained in the previous sections. More details can be found in Chow and Shao^[5] and Chow and Liu.^[6]

Substantial Evidence with a single Trial

An important application of the results derived in the previous sections is to address the following question: is it necessary to conduct a second clinical trial when the first trial produces a relatively strong positive clinical result (e.g., a relatively small p -value is observed)? As indicated earlier, the FDAMA of 1997 includes a provision stating that under certain circumstances, data from one adequate and well-controlled clinical investigation and confirmatory evidence may be sufficient to establish effectiveness for risk/benefit assessment of drug and biological candidates for approval. This provision essentially codified an FDA policy that had existed for several years but whose application had been limited to some biological products approved by the Center for Biologic Evaluation and Research (CBER) of the FDA and a few pharmaceuticals, especially orphan drugs such as zidovudine and lamotrigine. As can be observed in Table 1, a relatively strong significant result observed from a single clinical trial (say, the p -value is less than 0.001) would have about 90% chance of reproducing the result in future clinical trials. Consequently, a single clinical trial is sufficient to provide substantial evidence for demonstration of efficacy and safety of the medication under study. In 1998, FDA published a guidance which shed the light on this approach despite that the FDA has recognized that advances in sciences and practice of drug development may permit an expanded role for the single controlled trial in contemporary clinical development.^[1]

Suppose that it is agreed that the second trial is not needed if the probability for reproducing a positive clinical result in the second trial is equal to or higher than 90%. If a positive clinical result is observed in the first trial and the confidence bound $\hat{P}_-$ is equal to or higher than 90%, then we have 95% statistical assurance that, with a probability of at least 90%, the positive result will be reproduced in the second trial. For example, under the two-group parallel design with a common unknown variance and $n = 40$, the

95% lower confidence bound $\hat{P}_-$ given by Eq. 20 is equal to or higher than 90% if and only if $|T(x)| \geq 5.7$, i.e., the clinical result in the first trial is highly significant. Alternatively, if the Bayesian approach is applied to the same situation, the reproducibility probability in Eq. 23 is equal to or higher than 90% if and only if $|T(x)| \geq 3.96$.

On the other hand, if the reproducibility probability is very low (e.g., $\hat{P}$ in Eq. 11 is less than 50%), it may also indicate that a clinically meaningful difference between the placebo and the drug product under study cannot be detected through the intended trials and, thus, there is no need to run the second trial.

Reproducibility Probabilities for K Trials

Consider the situation where a number of clinical trials are conducted in a sequential manner. Our interest is the reproducibility probability for the k th trial, given that all previous $k - 1$ trials produce positive clinical results.

The extension of the results under the Bayesian approach is straightforward. Let $\pi_0(\theta | x_0) = \pi(\theta)$ be the prior for θ (which is usually a noninformative prior) and $\pi_k(\theta | x_k)$ be the posterior after observing the data from the k th trial, $k = 1, 2, \dots$. Then $\pi_k(\theta | x_k)$ can be used as the prior for the $(k + 1)$ th trial. The reproducibility probability for the $(k + 1)$ th trial is

$$P(|T| > c | x_k) = \int P(|T| > c | \theta) \pi_k(\theta | x_k) d\theta, \\ k = 0, 1, \dots$$

where x_k is the data set containing all data up to the k th trial,

For the non-Bayesian approach, the simplest way of constructing a reproducibility probability for the $(k + 1)$ th trial is to apply the procedures given in the sections “Reproducibility Probability” and “The Estimated Power Approach” with $x = x_k$, assuming that all trials have the same design.

Binary Data

In some clinical trials data are binary and μ_i' are proportions. Consider a two-group parallel design. For binary data, sample sizes n_1 and n_2 are usually large so that the Central Limit Theorem can be applied to sample proportions $\bar{x}_1$ and $\bar{x}_2$, i.e., $\hat{x}_i$ is approximately $N(\mu_i, \mu_i(1 - \mu_i)/n_i)$. Thus the results in the sections “The Estimated Power Approach,” “The Confidence Bound Approach,” and “The Bayesian Approach” for the case of unequal variances with large n can be applied.

CONCLUSION

In clinical research, it is of interest to determine whether the observed clinical results are reproducible. The assessment of reproducibility probability using the estimated power approach, confidence bound approach, or Bayesian

approach is helpful. The reproducibility probability could be a useful indication for regulatory review/approval of the drug product under investigation.

Clinical Trial Design: Statistical Assurance

Shuyen Ho

Global Data Operations, PAREXEL International, Durham, North Carolina, U.S.A.

Abstract

The frequentist statistical power is the probability of rejecting the null hypothesis with a prespecified true clinical treatment effect. As such, power is a conditional probability conditioned on the true but actually unknown effect. The Bayesian statistical assurance is an unconditional probability of rejecting the null hypothesis, given a prior probability distribution of the unknown treatment effect. In this entry, we provide a brief description of assurance and illustrate its computation by a simple two-sample normal example.

Keywords: Statistical power; Assurance; Probability of success; Bayesian prior distribution; Conditional and unconditional probability; Bayesian clinical trial simulation.

INTRODUCTION

Traditional (frequentist) clinical trial design uses statistical power to indicate how likely a trial is going to be successful. However, more often than not, the power is rarely a precise indicator of trial success because power is simply a conditional probability that is given a fixed parameter value. In the Bayesian framework, a parameter is characterized by a probability distribution, therefore similar to the expected value of a random variable being the integral of the random variable with respect to its probability distribution; assurance is defined as an expected power with respect to a probability distribution of the unknown parameter. Assurance in clinical trial design can be useful for internal decisions.

BACKGROUND

The concept of assurance (O'Hagan and Stevens^[1]), also called “expected power” or “average power,” appeared earlier in the studies by Spiegelhalter and Freedman^[2] and Gillett^[3] and “averaged success probability” later in the study by Chuang-Stein.^[4] Also a similar concept of “reproducibility probability” using priors in assessing the success probability before replicating a clinical trial appeared in the study by Shao and Chow.^[5]

Assurance in clinical trial design was first referred by O'Hagan, Stevens, and Campbell^[6] where they “argue that assurance is an important measure of the practical utility of a proposed trial, and indeed that it will often be appropriate to choose the size of the sample (and perhaps other aspects of the design) to achieve a desired assurance, rather than to achieve a desired power conditional on an assumed treatment effect.”

A BASIC EXAMPLE

We illustrate the assurance concept by the basic two-sample hypothesis testing example from the study by O'Hagan, Stevens, and Campbell.^[6]

Suppose that in a two-treatment clinical trial with n_i patients randomized to treatment i ($i = 1, 2$), the continuous outcome x_{ij} from j^{th} patient is normally distributed as $x_{ij} \sim N(\mu_i, \sigma_i^2)$. Assuming that σ_i^2 is known, we estimate the population means with the sample means as $\bar{x}_i \sim N(\mu_i, \sigma_i^2 / n_i)$. Then, the treatment difference $\delta = \mu_1 - \mu_2$ can be estimated by $\hat{\delta} = \bar{x}_1 - \bar{x}_2$ and the standard deviation can be calculated as:

$$\tau = \sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}, \text{ i.e., } \hat{\delta} = \bar{x}_1 - \bar{x}_2 \sim N(\delta, \tau^2) \quad (1)$$

The statistical power is then calculated based on this distribution that is a conditional distribution on the unknown treatment difference δ . In a two-sided superiority trial to test the null hypothesis $H_0: \delta = 0$ against the two-sided alternative $H_a: \delta \neq 0$, the null hypothesis is rejected if $|\bar{x}_1 - \bar{x}_2| > \tau Z_{\alpha/2}$, where $Z_{\alpha/2}$ is the upper $\alpha/2$ significance point of the standard normal distribution.

The power is:

$$\begin{aligned} &P(\text{null hypothesis is rejected}) \\ &= P\left(\bar{x}_1 - \bar{x}_2 > \tau Z_{\alpha/2}\right) + P\left(\bar{x}_1 - \bar{x}_2 < -\tau Z_{\alpha/2}\right) \\ &= \Phi\left(-Z_{\alpha/2} + \delta / \tau\right) + \Phi\left(-Z_{\alpha/2} - \delta / \tau\right) \end{aligned} \quad (2)$$

The assurance is then defined based on the expected power with a prior distribution on this unknown parameter δ . Using

Fig. 1 Case 1: Given $\delta = 0.5$, $\tau = 0.65$, $n_1 = n_2 = 35$, power = 90%; $\delta \sim N(0.5, 0.69^2)$, assurance = 61%

a commonly used conjugated prior normal distribution from previous clinical trials as $\delta \sim N(m, v)$, the unconditional distribution can be obtained as $\bar{x}_1 - \bar{x}_2 \sim N(m, \tau^2 + v)$. The assurance that the null hypothesis is rejected can be formulated based on the unconditional distribution of $\bar{x}_1 - \bar{x}_2 \sim N(m, \tau^2 + v)$ as:

$$\begin{aligned} \gamma &= P(\text{null hypothesis is rejected}) \\ &= P\left(\bar{x}_1 - \bar{x}_2 > \tau Z_{\alpha/2}\right) + P\left(\bar{x}_1 - \bar{x}_2 < -\tau Z_{\alpha/2}\right) \\ &= \Phi\left(\frac{-\tau Z_{\alpha/2} + m}{\sqrt{\tau^2 + v}}\right) + \Phi\left(\frac{-\tau Z_{\alpha/2} - m}{\sqrt{\tau^2 + v}}\right) \end{aligned} \quad (3)$$

Now let us look at a couple of specific cases.

Case 1: If the true treatment effect $\delta = 0.5$, $\tau = 0.65$, sample size = 35 per group, and $\alpha = 0.05$, then the power is 0.9 (90%). If the prior distribution for $\delta \sim N(0.5, 0.69^2)$, then the assurance is 0.61 (61%), as illustrated in Fig. 1.

Case 2: Same as case 1, but change the prior mean to 0.2 so $\delta \sim N(0.2, 0.69^2)$, then the assurance becomes 0.44 (44%), as illustrated in Fig. 2.

As can be seen from these two cases, the prior of δ has a major impact on assurance. This is similar to other Bayesian

Fig. 2 Case 2: Given $\delta = 0.5$, $\tau = 0.65$, $n_1 = n_2 = 35$, power = 90%; $\delta \sim N(0.2, 0.69^2)$, assurance = 44%

approaches using informative priors. Therefore, it is crucial to obtain a relevant and defensible prior distribution for the parameter(s); otherwise, it can be misleading and hinder informed and appropriate clinical trial decisions.

There are generally two ways of obtaining the most relevant priors, one is by data-driven, for example, as in the study by Novick, Ho, and Best,^[7] and the other is using prior elicitation as in the studies by Garthwaite, Kadane, and O'Hagan^[8] and Oakley and O'Hagan.^[9] Generally speaking, data-driven methods rely on historical data and analytical tools, whereas the prior elicitation would include experts' perspectives on historical data, as well as their subjective personal beliefs. Because different priors produce different assurances, when there is limited and consistent historical data, data-driven methods can be recommended. However, if historical data are not consistent and/or abundant, then prior elicitation or some other forms of reconciliation will be recommended.

One of the major differences between power and assurance is on their asymptotic properties. For power, due to its conditional on a fixed parameter value, when sample size increases to infinity, the power approaches to 100%. This is undesirable because it undermines the clinical meaningfulness in which one can always try to increase sample size in order to achieve statistical significant test results, regardless of whether the effect is practically meaningful or not. On the other hand, the assurance is unconditional and based on a prior distribution of the parameter(s); therefore, it is bounded by the probability of positive outcomes. This can be seen from the assurance formula, Eq. 3. As study sample sizes n_1 and n_2 approach infinity, the standard error τ approaches zero and then the assurance approaches:

$$\gamma = 2\Phi\left(\frac{m}{\sqrt{v}}\right) \quad (4)$$

This is the prior probability of rejecting the null hypothesis, i.e., prior probability of positive outcomes. This nice property tells that in reality, there should always be some probability for non-positive outcomes, and therefore, it is impossible to be 100% assured of positive outcomes, unless the prior probability distribution for the parameter(s) does not cover any non-positive outcomes. In this extreme case, there will be little point to conduct a new clinical trial because the success has already been perceived and reflected in the prior distribution of the parameter(s).

ASSURANCE BY SIMULATION

For priors that are not conjugate or obtained from prior elicitation, or for priors that involve multiple parameters, there are usually no closed forms for their corresponding posterior distributions. In these cases, assurance can be obtained by simulations such as Bayesian Clinical Trial Simulation by O'Hagan, Stevens, and Campbell^[6] or Monte-Carlo Simulation-Based simulations by Chen and Ho.^[10]

APPLICATION OF ASSURANCE

The assurance concept can be applied to various designs such as non-inferiority, equivalence, and cost-effectiveness where trial success is more complicatedly defined. Assurance can also be applied to any meaningful outcome of a trial and need not have any direct connection to power. For these generalizations, the study by O'Hagan, Stevens, and Campbell^[6] is referred.

CONCLUSION

In the real world of clinical trials, the assurance can provide a more realistic and robust measure of probability of success than the traditional power can. Assurance does depend on the prior distribution of treatment effects; therefore, it is crucial to have appropriate priors that closely reflect historical data and/or experts' expertise. Assurance typically is used for internal decisions by the pharmaceutical industry sponsors. Good decision-making is important for clinical development, and therefore, methods such as assurance can be beneficial to patients, sponsors, and regulators as well as society in general.

ACKNOWLEDGMENT

The author would like to thank Dr. Yin Yin for help with the figures.

Abstract

We discuss four clinical trial designs using prospective patient population enrichment—placebo lead-in, randomized withdrawal, sequential parallel comparison design (SPCD), and two-way enriched design (TED). All designs are two-stage designs. In the placebo run-in and randomized withdrawal, the first stage is usually shorter and data from the first stage is not used in the primary efficacy analysis. In the SPCD and TED, both stages are randomized, double-blind, and placebo-controlled, and data from both stages are used in the primary efficacy analysis.

Keywords: Placebo response; Placebo run-in; Placebo lead-in; Randomized withdrawal; SPCD; TED.

INTRODUCTION

The randomized, double-blind, placebo-controlled clinical trial is the gold standard of evidence-based medicine, informing individual patient and prescriber about therapeutic choices. In a randomized trial, randomization and blinding remove treatment allocation bias, provide the foundation for clinical and statistical inference, and promote the balance of known and unknown covariates between intervention arms. By design, clinical trials target a sample of patients with a specific health condition, who are able and willing to participate in the evaluation of the investigational intervention (drug, device, other medical, or non-medical treatment). The appropriate target patient population for a clinical trial is defined using demographic and diagnostic criteria, severity and time course of disease, response to past treatment attempts, co-morbidity, and co-medication. For evident ethical, medical, scientific, and operational reasons, the clinical trial is not a random sample of a defined general source population, and all patient populations enrolled in clinical trials are implicitly “enriched.” The clinical trial designs described in this entry represent prospective enrichment of the clinical trial patient population based on outcomes observed during the trial.

The U.S. Food and Drug Administration (FDA) defines enrichment in the context of clinical trial design as “the prospective use of any patient characteristic to select a study population in which detection of a drug effect (if one

is in fact present) is more likely than it would be in an unselected population.” Demographical, pathophysiological, historical, genetic or proteomic, clinical, and psychological characteristics have been used for enrichment.^[1]

Enrichment strategies and objectives can include the following:

1. To reduce interpatient variability, by restricting the baseline characteristics of the study population to a narrow range (thus reducing the impact of potential confounding variables) and excluding patients who are at high risk of non-compliance.
2. To reduce inpatient variability, by excluding patients who exhibit marked fluctuations and variability in disease-related symptoms and parameters at baseline.
3. To reduce the potential impact of missing data, by excluding patients who are at high risk of missing study visits or early drop out (whether due to poor tolerability or other factors).
4. To select a subgroup of patients who are more likely to respond to the intervention than the general population as a whole (“predictive enrichment”), based on the following selection criteria:
 - a. presence of a physiologic or disease characteristic that indicates potential sensitivity to the intervention, for example, the presence of a biomarker, proteomic marker, presence of a sensitive microorganism for an anti-infective, etc.

- b. prospective or historic documented response to the intervention under study or to another intervention with a similar mechanism of action.
5. To reduce the potential adverse impact of a high placebo response rate on efficacy signal detection, by excluding patients who exhibit a response to prospective treatment with placebo.
6. To maximize the end point event rate in the study, by enrolling patients with prognostic factors that indicate a high probability of an end point event occurring while on study ("prognostic enrichment").

The potential benefits of enrichment strategies can thus be summarized as follows:

1. Enhancement of internal validity, achieved by good control over confounding variables and the incidence of missing data.
2. Decrease in end point data variability, resulting in an increase in statistical power and a decrease in sample size required.
3. The avoidance of exposing patients to experimental interventions to which they are unlikely to respond and may not tolerate well.

The potential disadvantage of enrichment is the difficulty in generalizing or extrapolating data generated in an enriched target patient population to a broader target patient population. In essence, the gains in internal validity conferred by enrichment are often achieved at the expense of losses in external validity.

Four different enrichment designs are discussed herein (placebo lead-in, sequential parallel comparison design [SPCD], two-way enriched design [TED], and randomized withdrawal). The first three designs involve enrichment for patients who have been shown not to respond to placebo. These are of value in situations where a high placebo response in the general patient population is likely to compromise signal detection. Randomized withdrawal features enrichment with patients who have already exhibited a response to active treatment during an open-label active lead-in. This design is used typically for longer term clinical studies to demonstrate persistence of efficacy and long-term safety.

ENRICHMENT ON THE BASIS OF PLACEBO NON-RESPONSE

Placebo is the optimal clinical trial reference group to evaluate a therapeutic response, where acceptable from an ethical standpoint. A placebo control group enables the evaluation of the absolute effect of drug treatment (from both efficacy and safety perspectives), with intrinsic assurance of assay sensitivity and minimization of expectation bias.^[2]

However, the steady rise of placebo response and patient heterogeneity, since the 1980s, to the current high levels observed in many clinical trials across a wide range of therapeutics and disease indication, has undermined assay sensitivity in many conventional single stage randomized, double-blind, placebo-controlled trials. High failure rates of therapeutic research and development threaten innovation and the economics at the heart of modern pharmaceutical, medical device, surgical, and non-medical health care. The result has also been an inability to replicate prior results in studies of well-established, efficacious therapeutic interventions, approved by regulatory authorities.^[3] The rise of placebo response has coincided with rapidly rising access to health care, health-related information, therapeutic interventions, and co-medication as well as profound changes in behavior, perceptions, and expectations among patients and investigators.

The very decision to enroll and stay in a clinical trial, and the change in exposure to health care and clinical trial procedures, can profoundly impact patient expectations, behavior and perceptions resulting in high placebo response and increased variability. This is true across many therapeutic areas, even in the presence of objective, quantitative diagnostic and therapeutic end points, such as in diabetes and arterial hypertension. Changes in behavior, expectations, and perceptions can influence the observed treatment response, assessed through objective as well as subjective end points, reported by patients, investigators, independent assessors, adjudicators, or dedicated service providers, including central laboratories, imaging, or signal information processing facilities. High placebo response has been observed in psychiatry, neurology, cardiovascular, pulmonary, gastrointestinal, hepatobiliary, musculoskeletal, endocrinological, urogenital, inflammatory, immunological, and other disease indications.

Attempts to address rising placebo response and decreasing separation between response to active treatment and placebo include compensation by sample size increases in fixed and adaptive trial design, enrichment on the basis of placebo non-response, and other measures designed to increase the accuracy and precision of patient diagnosis and end point assessment.

Study designs featuring enrichment on the basis of placebo non-response include the placebo lead-in design, the SPCD, and the TED options, as discussed below. The rationale for placebo non-responder enrichment is that patients who have failed to respond during a prospective period of placebo treatment may be less likely to exhibit a placebo response in a subsequent randomized, double-blind period of active treatment versus placebo. It is anticipated that a lower placebo response in the enriched population should enhance the ability of the study to detect an efficacy signal. However, the ability to demonstrate a separation between active and placebo in this enriched population will depend on the degree to which placebo non-responders can be separated from placebo responders during the lead-in.

Fig. 1 Placebo lead-in design. Primary efficacy analysis set is in gray

PLACEBO LEAD-IN DESIGN

The primary objective of a placebo lead-in design (Fig. 1) is to improve trial assay sensitivity by reducing the excessive background noise generated by placebo response.

A placebo lead-in trial (also referred to as placebo run-in) consists of an initial stage in which all consented patients are exposed to placebo during a fixed or variable open-label, single- or double-blind period. At the end of the lead-in, placebo non-responders are admitted to the single randomized, double-blind controlled stage. Placebo responders do not enter the randomized stage of the trial. Placebo lead-ins serve the following objectives:^[4]

- weeding out non-compliers before randomization
- ensuring that patients are stable
- washing out previous treatment
- provide a period for baseline measurement, and
- eliminating placebo non-responders

There is uncertainty as to whether or not placebo lead-in design is successful in reducing placebo response and increasing the observed treatment. Chen, Yang, and Hung^[5] reported that trials with placebo lead-in yielded slightly lower placebo response in the randomized phase compared

to trials without a lead-in. Trivedi and Rush^[6] conducted a meta-analysis of a number of single-blind placebo lead-in trials in major depressive disorder and showed that placebo lead-ins did neither decrease placebo response nor increased the separation between active and placebo. Among the possible explanations is the patients’ and investigators’ awareness of the lead-in stage, even single- or double-blind, which may unconsciously or consciously influence their behavior, expectations, adherence, co-intervention/co-medication usage, observation, or reporting.

SPCD

The SPCD was proposed by Fava et al.^[7] It consists of two consecutive randomized, double-blind, placebo-controlled stages, often of equal duration, with continuity of exposure, observation, and blinding for all patients and investigators. Stage 1 is conducted in a non-enriched patient population, whereas stage 2 provides data from an enriched population of placebo non-responders identified in stage 1. At the end of stage 1, placebo non-responders are re-randomized in equal proportions to receive active treatment or placebo in stage 2 (Fig. 2). Placebo responders are often re-randomized to receive active treatment or placebo in stage 2. This can provide additional insights into the nature and persistence of the placebo response and its impact upon signal detection. Patients randomized to active treatment in stage 1 may continue on active treatment in stage 2. This provides the opportunity to evaluate the efficacy and safety of the active treatment over a longer exposure period. Consider a SPCD trial where two-third of patients receive placebo in stage 1, all patients receiving placebo are re-randomized between active and placebo in stage 2, and patients who received active treatment in stage 1 continue on active in stage 2. In this trial, one-third of all patients will receive placebo during both stages of SPCD

Fig. 2 Sequential parallel comparison design. Primary efficacy analysis set is in gray

and one-third of the patients will receive active treatment during both stages, providing data for active placebo comparison over a period of time that is twice as long as the length of a single stage.

As an alternative to re-randomization, treatment allocations for both stages can be determined in the initial randomization at the start of the study. This option is simpler from a trial, randomization and clinical supply management perspective but, unlike re-randomization at the end of stage 1, it does not provide assurance of balanced groups in stage 2.

The continuity of investigators' and patients' blinding is maintained throughout both SPCD stages through the use of an appropriately masked protocol, and patient informed consent disclosure mentioning the fact of randomization, but concealing the specific details of stages, their respective admission criteria, as well as times of randomization and end point assessment. Boessen, Knol, and Groenwold^[8] proposed to use SPCD with variable stage duration to further facilitate masking of patients and investigators.

The primary analysis set includes all-comer patient data from stage 1 as well as stage 2 data from stage 1 placebo non-responders (Fig. 2). The null hypothesis is that there is no treatment effect in the stage 1 population of all-comers and there is no treatment effect in the population of placebo non-responders. The combined treatment effect across both stages is defined as the weighted sum of effect estimates from stages 1 and 2, using a prespecified weight. Dividing this weighted sum of estimates by its standard error leads to an asymptotically normally distributed test statistic, which is used to test the null hypothesis and calculate the associated p value. Methods of analyzing the SPCD data with continuous end point have been discussed by Tamura and Huang;^[9] Chen, Yang, and Hung;^[5] Doros, Pencina, and Rybin;^[10] and Chi et al.^[11] Methods to combine data from the two stages of SPCD have been proposed for binary outcomes.^[7,12,13] Wang and Ivanova^[14] investigated the possibility of changing the allocation proportion or dropping arms in a SPCD trial with multiple arms and Silverman and Ivanova^[15] investigated sample size re-estimation strategies and other adaptations in a SPCD trial.

SPCD is suited for clinical trials in which it is ethically and medically acceptable and feasible to expose and observe patients during two consecutive stages. SPCD avoids the issue of carryover effect which biases the evaluation of many crossover trials, as no patient crosses over from receiving active treatment in this design. Baer and Ivanova^[16] reviewed results of several completed SPCD studies. Results from multiple SPCD trials have been reported in peer-reviewed journals, including five studies in major depressive disorder^[17–20] and one study of agitation and aggression in Alzheimer's dementia patients.^[21] In most studies, the placebo response was reduced in stage 2 compared to stage 1, thus demonstrating the effectiveness of SPCD stage 1 in identifying placebo non-responders

as well as the continued lower placebo response among stage 1 placebo non-responders in stage 2.

THE RANDOMIZED WITHDRAWAL TRIAL DESIGN

Responders to be enrolled in a randomized withdrawal study are identified in an open-label single arm treatment period or the active arm of a controlled clinical study. Patients are randomized to continue receiving active treatment or to switch to placebo.^[22] The primary efficacy end point is typically time to relapse/recurrence (return of symptoms). Patients experiencing relapse/recurrence are removed from the study immediately and receive appropriate standard of care.^[2]

The randomized withdrawal design is useful in providing information on the persistence and durability of efficacy effects, optimal duration of treatment, and safety during longer term treatment. In addition, randomized withdrawal studies with multiple dose arms can be used to provide information on the optimal maintenance dose. From an ethical perspective, the randomized withdrawal design may offer some benefits, compared to conventional long-term placebo-controlled studies, because relapse/recurrence leads automatically to immediate withdrawal and transfer to appropriate standard of care (which entails only a short period of poor response associated with placebo treatment).

When designing a randomized withdrawal study, the potential impact of selection and attrition bias, the development of tolerance during the open-label active lead-in stage, the potential for carryover effects from the lead-in to the randomized stage, as well as withdrawal and rebound in the second, randomized stage have to be considered carefully. Patients who develop tolerance may derive little or no ongoing benefit from continuing active treatment during the open-label lead-in or the randomized stage. Patients may also experience withdrawal symptoms and/or rebound disease exacerbation when active treatment is discontinued in stage 2, upon switching to placebo. These effects can lead to differential adherence and retention as well as safety, tolerability, or efficacy signs and symptoms potentially unblinding patients or investigators and biasing observation and reporting. These sources of bias may result in an erroneous evaluation of the therapeutic benefit–risk. If an intervention is known to exhibit tolerance, withdrawal, and/or rebound phenomena, the potential impact upon the study results may be mitigated by slowly tapering off of the dose in those patients randomized to placebo.

Randomized withdrawal studies are inherently enriched with active responders and exclude patients who are unable to tolerate the intervention. Hence, the efficacy and safety profiles obtained in such studies are expected to be more favorable than would be the case in a general, unselected population.

Fig. 3 TED. Primary efficacy analysis set is in gray

TED

The TED^[23] can be viewed as a combination of the parallel design, placebo run-in, and randomized withdrawal (Fig. 3). It is an extension of the SPCD that, in addition, re-randomizes stage 1 active arm responders in the second stage to active and placebo exposure and utilizes information from this patient cohort versus the placebo non-responders in the overall active placebo comparison. Patients who respond to active treatment are examined to see whether the maintenance of response is different between those patients switched to placebo versus those who remain on active.

Ivanova and Tamura^[23] describe the analysis methodology for TED trials with binary outcomes. An overall test of the treatment effect in all-comers, placebo non-responders, and active treatment responders is presented.

CONCLUSION

Enrichment trial designs are increasingly important to detect an accurate and reliable efficacy signal in the appropriate target patient population, especially, in the presence of placebo response and high heterogeneity among patients. All trials are enriched in the process of selecting and admitting patients, according to diagnostic, prognostic, predictive, and inclusion/exclusion criteria. We define enrichment trials as those in which an explicit and prospective selection occurs during the trial, based on the patient's response to the investigational intervention. All designs described are two-stage designs. In the placebo lead-in and randomized withdrawal designs, the first stage is usually shorter, non-randomized, and uncontrolled, and only the data from the second stage contribute to the primary efficacy analysis. In SPCD and TED, both stages are

randomized, double-blind, and placebo-controlled. The two stages are often, but not necessarily, of the same duration, and data from both stages contribute to the primary efficacy analysis. The relative power of these designs for a given sample size depends on the treatment responses and their variability in all-comers, placebo non-responders, and, in TED, active responders, as well as on the proportion of placebo non-responders and active responders. Generally, SPCD and TED have higher power, given equal assumptions, as some of the patients contribute two data points to the primary efficacy analysis, and a larger treatment effect is expected in the second stage.

Clinical Trial Process

Paul F. Kramer

Bristol-Myers Squibb Company, Plainsboro, New Jersey, U.S.A.

Abstract

This entry outlines the importance of monitoring the effects of implementing changes in work processes based on the conclusions from the information gathered and explores the importance of continually looking for answers, acting on what was learned, and monitoring the effects of process changes.

INTRODUCTION

Regardless of the setting—whether a research group in an academic or healthcare institution, or a research and development organization in a small venture capital-based or large multinational pharmaceutical company—there are forces that demand these organizations, and their members, to respond successfully to the following question: How can more be done with the same resources in shorter time periods with no significant reduction in the quality of the output of the activity? The challenge this question poses to clinical research is now a routine part of the activities in most pharmaceutical companies. With aggressive commitments from the corporate offices to increase dramatically the number of new compounds entering and completing the clinical research and development process, all members of the research team are being affected.

This entry will (1) outline the types of information necessary for finding answers to this vexing question; (2) outline assessments of what was learned during information gathering; (3) outline the importance of monitoring the effects of implementing changes in work processes based on the conclusions from the information gathered; and (4) explore the importance of continually looking for answers, acting on what was learned, and monitoring the effects of process changes.

OVERVIEW

At a basic level, finding out how more can be done with the same resources involves using the steps in the scientific method that are familiar to many readers. That is, gather facts, data, observations, and related information concerning the topic under investigation; articulate a problem based on what is known; develop a hypothesis surrounding the problem; design an appropriate methodology that will test the hypothesis; execute the methodology to generate data; analyze and evaluate the data to test the hypothesis;

and draw appropriate conclusions. As will be discussed later, another parallel to the scientific method is that the critical endpoint is not only the conclusion, but also the successful application of the conclusion. The application of conclusions may be to provide a practical solution to the problem that was articulated or to use the new data and insights to define the problem better, to develop and test a more refined hypothesis, and to derive added conclusions to follow along a path of continuous improvement.

UNDERSTANDING WORK PROCESSES

In order to answer the question introduced in the preceding section, it is critical to develop a context by defining what tasks need to be accomplished and what the output is from those tasks. The thoroughness of describing the process, the output(s), and the tasks needed to accomplish them will determine the success of the information-gathering step.

Gathering Information

Understanding the work processes is not the endpoint but just the beginning. Some of the information needed to understand a work process include the following.

Define the Starting Point for the Process

What is the starting point? What are the decisions or events that trigger the initiation of the process? Who makes the decision to start, and how is it communicated? Who is responsible for the process or who owns it? What material or information is required to begin the process?

Define the End of the Process

What is the ultimate, final output of the completed process? Who is the customer for the final output? How is

the customer organizationally related to the person(s) or group(s) responsible for the process? How is the final output delivered? How do you know that the output is ready for delivery? How do you measure and report on the success, or lack of success, of the final output? How is the feedback concerning the output received from the customer?

Define the Tasks in a Process

Identify and be able to describe each task required to complete a process. Identify who is responsible for a task or who owns it. Is the owner inside or outside of the group responsible for completing the task? What event(s), task(s), information, material(s), or decision(s) are required to begin each task? How are the necessary information, material(s), or decision(s) received? What resources—e.g., persons, equipment, and systems—are required to complete each task? For intermediate outputs, to whom is the output delivered? For intermediate outputs, how is the product of the task delivered to the person or group responsible for the next task? Which tasks need to be completed before the next task can begin? Which tasks can be completed in parallel with or independent of other tasks in the process?

Define Intermediate Outputs or Milestones

Are there any intermediate outputs that must be achieved prior to the final output? What are the intermediate outputs? Who is the customer for (who receives) each intermediate output? How is the customer organizationally related to the persons or groups responsible for the tasks to achieve each output? How is the feedback concerning the adequacy of the output received? How do you measure and report on the success, or lack thereof, of each intermediate output? What milestones are meaningful to the management?

Assessing the Information

In order to understand the work processes, the information and data gathered must be assessed to define or refine the statement of the problem and to develop a statement of the hypothesis. The following topics should be considered during work process assessment.

Assess the Starting Point for the Process

Evaluate the decisions or events that trigger the initiation of the process to determine if there is a predictable pattern. Describe the adequacy, or lack thereof, of the systems for transmitting the decision to start and providing the material or information that is required to begin. Define what information the person(s) or group(s) responsible for the process actually need to start the process. Describe what happens if the decision to start or the material or

information that is required to begin is not adequately delivered or communicated. What control or influence, if any, can be exercised by the process owner at the starting point? How can those items that are within the area of authority of the process owner be controlled, influenced, or managed by that person? How can the resources within the area of authority of the process owner be affected by decisions or activities outside the owner's area of authority? For those areas of authority that cannot be controlled or influenced by the process owner, what steps can be taken to manage the impact when those areas do not support, or prove inadequate for, the process?

Assess the End of the Process

Describe the characteristics of the output that will satisfy the customers' requirements. Describe the adequacy, or lack thereof, of the systems for delivering the output to the customer. Describe the monitoring systems, if any, that can predict if the output will meet the required quality and the delivery schedule. Describe what happens if the output is delivered sooner than scheduled, if the delivery is delayed, and if the quality is unsatisfactory to the customer or it does not meet the needs of the customer. What control or influence, if any, can be exercised by the process owner at the end of the process? Does the current process work to achieve the desired output, within the desired time schedule, with the systems and resources currently available?

Assess the Tasks Involved in the Process

Categorize the importance of each task to the completion of the process. Is each moderately or significantly important task well understood? What is needed to start the task? Who provides what is needed, and how? Who executes the task? What resources are needed? How and to whom is the product of the task delivered? Define the tasks on the critical path in the process. What are the dependencies between tasks, e.g., which task(s) have to be completed before another specific task can begin or can be completed in parallel with or independent of the other tasks in the process? Describe the adequacy, or lack thereof, of the systems for transmitting the material or information that is required to begin the task. Define what information the person(s) responsible for the task actually need to start the task. Describe what happens if the material or information that is required to begin is not adequately delivered or communicated. What control or influence, if any, can be exercised on the task by the process or task owner? How can those items that are within the area of authority of the task owner be controlled, influenced, or managed by that person to facilitate task completion? How can the resources within the area of authority of the task owner be affected by the decisions or activities outside the owner's area of authority? For those

areas of authority that cannot be controlled or influenced by the task owner, what steps can be taken to manage the impact when those areas do not support, or prove inadequate for, the process?

Assess the Intermediate Outputs or Milestones

Describe the requirements the output must achieve. Describe the systems, if any, that can monitor whether the output will meet the required quality and delivery schedule. Describe what happens if the output is delivered sooner than scheduled, if the delivery is delayed, or if the quality is unsatisfactory. Do the current tasks work to achieve each of the desired intermediate outputs, within the desired time schedule, with the systems and resources currently available?

Prepare a Statement of Problems

Based on a clear understanding of the work process, output(s), and tasks, the next step would be to identify specific problems that could result from work inefficiencies, poor resource utilization, unnecessary or redundant tasks, or low work capacity. Because the objective of these steps is to determine how to do more with the same, avoid focusing on inadequate resources, especially human resources, as a primary problem. Attempt to look beyond this often simplistic statement of the problem. Inadequate resources are a valid problem if you have metrics and benchmarking information to substantiate your conclusions or if the focus of the problem involves equipment or technology that enables increased efficiency or increased work capacity for the available human resources.

The problem list must be prioritized to have the basis for decision making that will manage the limited resources available to explore and/or implement change in the process, output(s), or tasks. Prioritization can be based on one or more of the following parameters: whether the process or task(s) are within the area of authority of the owner (focus on change that is within the area of authority of the task or process owner); the magnitude of the resources and the period of time that will be required to implement the change successfully (look for problems with short-term, fairly easy solutions to build the confidence of the staff, management, and organization while working on other longer term solutions); the size of the benefit derived from the change to the strategic and/or operational goals of the organization (do not overlook the benefit derived by another part of the organization in addition to the portion implementing the change); objectives and goals established by the management (avoid undertaking work process change without having a well-defined, specific set of goals and objectives that have been agreed upon by the necessary levels of management).

From the list of problems, develop a potential solution for the priority problems chosen. The solution should

portray the proposed change and the resulting measurable benefit. This could resemble a statement of hypothesis; for example, by developing and implementing a common computer platform, duplicate entry of the same data into two different systems can be eliminated, thus reducing the processing time by *X* hr or allowing a *Y*% increase in the number of forms processed.

GATHERING DATA—MONITORING WORK PROCESSES

As with the scientific method, a crucial activity is to test the potential solution, or hypothesis, with a well-designed methodology and to capture data from the endpoints needed to test the solution. As already noted, when stating the solution, it is necessary to identify the measurement(s) that can be used to determine if the solution was successful (having preestablished goals for evaluating the solution is critical).

The term *metrics* is often used to refer to the data gathered while monitoring work processes or tasks. Metrics can include such items as the time elapsed for completing a task or process; the number of times a task must be repeated to achieve the standards required for the output; the rate at which the errors occur; and the objective feedback from the customer of the output.

As is true of clinical research, gathering data solely for the sake of having the data is a poor use of resources. There must be value that can be derived from the data. In the case of evaluating the work process, the value could include the following: providing the management with a real-time indication of critical conditions in a process or task; predicting whether the output will meet the standards or the delivery schedule; and identifying potential problems in a task or process to allow implementation of the required solution before there could be a significant delay or loss in quality. An issue that should be addressed when testing a potential solution is to assess the value of the metrics used to evaluate the process, output, or task. Some metrics may not be predictive of, or related to, the quality or efficiency of the output. Some metrics may be too complex to collect for use in routine assessment of a process.

CONTINUOUS WORK PROCESS IMPROVEMENT

The question introduced at the start of this entry of how more can be done with the same resources in shorter time periods with no significant reduction in the quality of the output of the activity includes an element of continuity. As potential solutions to work process problems are tested, a recurring set of events should be set in place. These events include the ongoing collection of metrics to describe and assess the work process, to identify previously undetected

or new problems, to refine insight into previously identified problems, to develop new or alternate solutions and the associated benefits, to implement and test the solutions, and to continue monitoring the process through meaningful metrics. Thus what may have started as a one-time exercise in doing more with the same, or even doing more with less, needs to become a routine part of the culture in which clinical research takes place.

CONCLUSION

Clinical trial process plays an important role in clinical research and development. It ensures not only the quality

of data collected from the trial, but also maintains the integrity of the trial within available resources and timeline. In addition, it enables upper management to make a critical go/no go decision during, or at the end of the process. In practice, it is suggested that tests or procedures employed at various critical stages of the process should be in compliance with good clinical practice (GCP) as specified in the International Conference on Harmonization (ICH) guideline.^[1]

Clinical Trial Simulation

Hung-Ir Li and Pan-Yu Lai

Allergan, Inc., Irvine, California, U.S.A.

Abstract

Clinical trial simulation utilizes the computer to simulate virtual patients in the clinical research context. This entry discusses how clinical trial simulation has been applied to better understand the physiology, pharmacology, properties, and performance of statistical and data analysis methods, and the possible trial outcomes to optimize clinical study design and clinical planning.

Keywords: Computer assisted study design; Model-based drug development; Modeling and simulation.

INTRODUCTION

In the new era of high technology, the traditional process for medical research and drug development has also evolved to become more time- and cost-effective. Clinical trial simulation, which utilizes the computer to simulate virtual patients in the clinical research context, has been applied to better understand the physiology, pharmacology, properties, and performance of statistical and data analysis methods, and the possible trial outcomes to optimize clinical study design and clinical planning. The concept of simulating clinical trials started in the late 1970s following the successful applications of simulation in the auto and aerospace industry. However, the application in the pharmaceutical industry to help the clinical development did not occur until the mid-1990s when computing and user-friendly trial simulation tools were developed. As of November 2000, more than 100 clinical trial simulations in more than seven therapeutic areas have been performed by more than 17 pharmaceutical companies.^[1] Applications include selecting the optimal dose, evaluating the effect of changes in formulation, dose regimen, or dosing route on changes in pharmacodynamic response, and so forth. Vigorous collaboration among regulatory agencies, academia, and industries continues through the twenty-first century, particularly in the United States. FDA Critical Path Initiative was launched in 2003 which promotes the innovation of the drug development and particularly encourages the best use of clinical trial simulation via the End-of-Phase-2A (EOP2A) pilot program beginning in 2004. The related Guidance for Industry: End-of-Phase-2A Meetings released in 2008 details the objectives and recommended utilities of clinical trial simulation in the exploration of trial design alternatives to increase the likelihood of future trial success.^[2–19]

WHAT IS A CLINICAL TRIAL SIMULATION?

Clinical trial simulation is a process that uses computers to mimic the conduct of a clinical trial by creating virtual patients and generating the outcomes for each virtual patient based on the prespecified models, preferably probabilistic but quite often deterministic models. These models include mathematical structures and estimates of the parameters or the corresponding variation or both. The simulated data are then analyzed to evaluate the properties of the clinical trial setting. The primary objective of a clinical trial simulation is to extrapolate or predict the clinical outcomes beyond the scope of previous studies from which the existing models were derived using the modeling techniques. It can also be used to verify or confirm the models depicting the relationships between the inputs such as dose, dosing time, patient characteristics, disease stage, and so forth, and the outcomes such as changes in the signs and symptoms, or time to events within the study domain. By evaluating the summarized virtual trial outcomes under various design scenarios, the impact of changes in formulation, dose regimen, or dosing route can be assessed. Initially, simulations use the distribution of patient characteristics to create virtual patients and the quantitative relationship between the patient characteristics, dose, and response to generate the outcome. Over the past decade, simulations have evolved to the current practice, which integrates the whole understanding of the disease physiology and pharmacological mechanism into a complex mathematical model to mimic human body responses to the treatment intervention. The simulation based on this integrated system of models will predict the potential clinical outcomes under different assumptions and various design scenarios, enabling a better selection or planning of the actual clinical trials.^[2–11] The resultant study design is often called the computer-assisted trial design (CATD). It improves

the cost-effectiveness and the timeliness of the clinical development process and expedites the availability of new therapies to the waiting patients. For example, to study an anti-obesity agent, one can build a model that includes the dosing regimen, the patient's daily activity, the caloric intake (food consumption including the percentage of fat), the insulin effect on the obese patients, the duration of the study, and the pharmacological mechanism of the agent, lipolysis, and energy expenditure. A clinical trial simulation can then be conducted to address the following questions: Does increased lipolysis lead to weight loss? Does exercise enhance drug efficacy? Which biomarker (such as fasting plasma free fatty acids levels or the respiratory quotient) is a more reliable measure of lipolysis? How does the plasma concentration of the investigational drug relate to tissue concentration and to the weight reduction? Does the type of food consumption influence the efficacy? How does the dosing regimen such as frequency, timing, and dose level affect the efficacy? What is the efficacy and safety profile compared to other marketed compounds?

APPLICATIONS AND SOME TOOLS

According to presentations at the U.S. Food and Drug Administration (FDA) Pharmaceutical Science Advisory Committee meeting in November 2000, more than 100 clinical trial simulations in more than seven therapeutic areas have been performed by more than 17 of the pharmaceutical companies.^[1] These applications include selecting the optimal dose; evaluating the effect of changes in formulation, dose regimen, or dosing route on changes in pharmacodynamic response; and integrating preclinical/clinical pharmacology and biopharmaceutics study results into late-phase clinical trials to ensure safe and effective study design, or unbiased, powered, and robust studies to maximize the treatment benefit/risk ratio. Further, the clinical trial simulation has become major part of the adaptive design, particularly the seamless phase II–phase III adaptive design, due to the complex nature of the adaptive design and the necessity of controlling the type I error rate.^[12] Therefore depending on the objectives, the required components for a clinical trial simulation can be as simple as a binomial variable, Dose/PK/PD modeling, or as complicated as an integration of all appropriate body compartments with the mechanism of actions of the compound. Sources for building these models can include (but are not limited to) all available data from the compound and literature review and the SBA (summary basis of approval) from the FDA of compounds in the same class (including animal data, pharmacokinetic/pharmacodynamic data, and biomarker/surrogate endpoints). When data are not available, models based on established theories and assumptions may be used and then updated later when data become available. Simulation is useful and helpful only when it is coupled with appropriate models. A negative

conclusion of a trial simulation can be the result of the lack of action of the compound, the improper specification of the model, or the improper study design strategy. The models used in the simulation need to be validated before and after the simulation is performed. There are more than 15 software packages for model-building and clinical trial simulations. These include NONMEM® by GloboMax LCC / NONMEM7™ by ICON Development Solution; WinNonlin®, WinNonMix®, and Pharsight Trial Simulator™ by Pharsight Corporation; S-PLUS® by Insightful; SAS® by SAS Institute; PhysioLab® by Entelos®; CellML™ and PathwayPrism™ by Physiome Sciences; and East® 5/SiZ® by Cytel Inc.

CLINICAL TRIAL SIMULATION IN REGULATORY DECISIONS

The regulatory agencies worldwide have recognized the promises of the clinical trial simulation in the drug development and been supportive in various venues since the twentieth century. The FDA Modernization Act of 1997 set the stage for the regulatory agency's proactive interaction with the industry toward common goals. The Critical Path Initiative was launched in 2003 which seeks not only changes in the science and technology of drug development but also the way FDA and Industry interact and share information. The FDA Guidance for Industry: Exposure-Response Relationships—Study Design, Data Analysis, and Regulatory Application and subsequently the FDA Guidance for Industry: End-of-Phase 2A Meeting (EOP2A) provide the scientific base and recommendations for clinical trial simulation and procedural details of FDA initiated forum in helping industry to streamline the drug development using clinical trial simulation.^[13,14] A pilot EOP2A program was initiated in 2004, which included various applications of clinical trial simulation in regulatory decisions such as basis for approval, labeling claims, designing trials, and setting policy. Examples include pediatric approval of trileptal without additional clinical trials, subgroup approval of zoledronic acid, and risk management of busulfan in pediatric patients.^[15–19] Similar regulatory interests in the application of clinical trial simulation have been observed in European Union and Japan.^[20,21]

CONCLUSION

Clinical trial simulation is a useful process to mimic human body responses to the treatment intervention by simulating clinical trials based on some pre-specified models before the clinical trials are launched. It is particularly useful in selecting the optimal dose, evaluating the effects of changes in formulation, dose regimen, dosing route on changes in pharmacodynamic response, and optimizing trial designs in clinical research and development.

It not only bridges the previous data to new trials using models but also checks the feasibility of the design of new trials to ensure an efficient and successful drug development. With the current high level of collaborations among academia, regulatory agencies, and industries, the clinical trial simulation has become the core of the model-based drug development in meeting the patient needs.

Clinical Trial Simulations: Earlier Development Phases

Mark Chang

Veristat, Southborough, Massachusetts, U.S.A.

Abstract

This entry discusses the simulation in early phases of clinical trials, specifically through oncology dose-escalation trials to discuss some theoretical and practical issues in trial simulations.

INTRODUCTION

Clinical trial simulation (CTS) is a powerful tool for designing, monitoring, and analyzing clinical trials. In recent years, simulation has been used in pharmacokinetic and pharmacodynamic modeling, assessing cardiologic abnormalities, and optimizing dose-finding strategies.^[1] In this section, we will study the simulation in early phases of clinical trials, specifically through oncology dose-escalation trials to discuss some theoretical and practical issues in trial simulations. We have chosen an oncology study, because of the following reasons.

1. Only a very small number of patients are allowed due to potential high toxicity of the test drug, and precise estimation of the dose-toxicity relationship is challenging.
2. The traditional escalation methods are an ad hoc approach.
3. There are many new approaches proposed using simulations.^[2–5]

Our intention is not to review or compare all the methods and make a recommendation, but to use several typical methods as vehicle to illustrate CTS.

OVERVIEW OF DOSE-ESCALATION TRIAL

Objectives of a Phase I Clinical Trial

The goal of the phase I trial is to characterize the safety profile of a new treatment in humans to set the basis for later investigations of efficacy and superiority, for example, in a cancer study, beginning treatment at a low dose very likely to be safe; so small cohorts of patients are treated at progressively higher doses until drug-related toxicity reaches a predetermined level. The primary objectives are to determine the maximum tolerated dose (MTD) of a drug for a specified regimen and to characterize the dose-limiting toxicity (DLT).

Population for Treatment

The phase I trial should define a standardized treatment regimen to be safely applied to humans and with some biological activities that are worth further investigation for efficacy. For non-life-threatening diseases, phase I trials are usually conducted with human volunteers, at least as long as the expected toxicity is mild and can be controlled without harm. In life-threatening diseases such as cancer or AIDS, phase I studies are conducted in patients because of the aggressiveness and possible harmfulness of treatments, possible systemic treatment effects, and the high interest in the new drug's efficacy in those patients.

Dose-Limited Toxicity and Maximum Tolerated Dose

Drug toxicity is considered tolerable if the toxicity is acceptable, manageable, and reversible. Common Terminology Criteria (CTC) established by the U.S. National Cancer Institute (NCI) is often used as the basis for defining a DLT. For example, in a cancer study, any AE from the CTC catalogue of grade 3 and higher related to treatment is considered a DLT. Often, a judgment of “possibly” and better is considered as drug-related toxicity. The MTD is defined as a dose level at which DLTs occurs with at least a certain frequency, e.g., 1/3.

Dose-Level Selection

The initial dose given to the first patients in a phase I study should be low enough to avoid severe toxicity. The commonly used starting dose is the dose at which 10% mortality (LD_{10}) occurs in mice. The subsequent dose levels are usually selected based on the following multiplicative set, $x_i = f_i \cdot x_{i-1}$ ($i = 1, 2, \dots, k$), where f_i is called the dose-escalation factor. Two popular sequences of dose-escalation factors are the so-called the Fibonacci numbers (2, 1.5, 1.67, 1.60, 1.63, 1.62, 1.62, ...) and modified Fibonacci numbers (2, 1.65, 1.52, 1.40, 1.33, 1.33, ...). The highest dose level in the trial should be selected such that it covers the biologically active dose.

Sample Size Per Dose Level

The number of patients to be treated per dose level should be small enough to limit any potential safety issues, but large enough to allow the investigators to determine the optimal dose levels. For oncology studies, recommendations vary between one and eight patients per dose level. Other suggestions include three to six patients per lower dose level or a minimum of three per dose level and a minimum of five near the MTD.

TRADITIONAL DOSE-ESCALATION DESIGN

There are usually 5 to 10 predetermined dose levels in an oncology dose-escalation study. The commonly employed dose-escalation rules are the traditional escalation rules (TER), which are also known as the “3 + 3” rule. The “3 + 3” rule can be described as follows:

1. Enter three patients at a new dose level.
2. Enter another three patients when one toxicity is observed; and
3. The assessment of the three or six patients will be performed to determine whether the trial should be stopped at that level or escalated to a higher dose level. Basically, there are two types of the “3 + 3” rules namely, TER and strict TER (or STER). TER do not allow dose deescalation, but STER do when two of three patients have DLTs (Fig. 1).

The “3 + 3” STER can be generalized to the $A + B$ TER and STER escalation rules. To introduce the traditional $A + B$ escalation rule, let A , B , C , D , and E be integers. The notation A/B indicates that there are A toxicity incidences out of B subjects and $>A/B$ means that there are more than A toxicity incidences out of B subjects. We assume that there are n predefined doses. In what follows, general $A + B$ designs with and without dose deescalation will be described. Lin and Shih^[6] derive close forms of some operating characteristics of general $A + B$ designs.

$A + B$ Escalation Without Dose Deescalation

The general $A + B$ designs without dose deescalation can be described as follows. Suppose that there are A patients at dose level i . If fewer than C/A patients have DLTs, then the dose is escalated to the next dose level $i + 1$. If more than D/A (where $D \geq C$) patients have DLTs, then the previous dose $i - 1$ will be considered the MTD. If no fewer than C/A but no more than D/A patients have DLTs, B more patients are treated at this dose level i . If no more than E (where $E \geq D$) of the total of $A + B$ patients have DLTs, then the dose is escalated. If more than E of the total of $A + B$ patients have DLT, then the previous dose $i - 1$ will be considered the MTD. It can be seen that the traditional “3 + 3”

Fig. 1 “3 + 3” Strict traditional escalation rule. (View this art in color at www.informaworld.com.)

design without dose deescalation is a special case of the general $A + B$ design with $A = B = 3$ and $C = D = E = 1$.

$A + B$ Escalation with Dose Deescalation

The general $A + B$ design with dose deescalation is similar to the design without dose deescalation; however, it permits more patients to be treated at a lower dose (i.e., dose deescalation), when excessive DLT incidences occur at the current dose level. The dose deescalation occurs when more than D/A (where $D \geq C$) or more than $E/(A + B)$ patients have DLTs at dose level i . In this case, B more patients will be treated at dose level $i - 1$, provided that only A patients have been previously treated at this prior dose. If more than A patients have already been treated previously, then dose $i - 1$ is the MTD. The deescalation may continue to the next dose level $i - 2$ and so on if necessary.

TWO-STAGE DOSE-ESCALATION DESIGN

Because of safety concerns, the starting dose is usually very low with minimal toxicity, and MTDs are often underestimated using the traditional escalation “3 + 3” rule, especially when there are many dose levels. An improved method is to use a two-stage escalation algorithm (TSER), where in the first stage, only a single patient is treated at

each dose level. When a DLT is observed, the traditional “3 + 3” rule will kick in. In what follows, we will compare TER and TSER using computer simulations.

EVALUATION OF DOSE-ESCALATION ALGORITHMS

There are advantages and disadvantages of different dose-escalation schemes. For example, the traditional “3 + 3” escalation is easy to apply, but the MTD estimation is usually biased, especially when there are many dose levels. The commonly used criteria for evaluating an escalation scheme are as follows. The expected number of patients is used to measure the efficiency of a trial. The number of DLTs is used to measure the safety protection of patients in the trial as a whole. Controlling the number of patients dosed above the MTD is to minimize the risk of all individuals in the trial. Mean predicted MTDs can be used to assess the accuracy of an algorithm. The dispersion of the predicted MTDs from simulations measures the precision of an algorithm.

SIMULATION EXAMPLE USING TER AND TSER

To choose an appropriate dose-escalation algorithm for a phase I oncology study to determine the MTD for a new test drug, computer simulations were conducted to compare the traditional “3 + 3” escalation rule and the two-stage escalation rule mentioned earlier. Based on results from preclinical studies, it was estimated that the toxicity (DLT rate) is 1% for the starting dose of 30 mg/m² (1/10 of the lethal dose). The DLT rate at the MTD was defined as 17% and the MTD was estimated to be 300 mg/m². The true dose toxicity was assumed to follow a logistic model, i.e., $\text{Logit}(p) = -4.952 + 0.011 \text{ Dose}$, where p is the probability of DLT or DLT rate. There were seven planned dose levels with a constant dose increment factor of 1.5. Only one dose level deescalation was allowed. Twenty thousand simulations were conducted using ExpDesign Studio^[5] for each of the two algorithms. The key results are compared in Tables 1 through 3.

The true MTD is somewhere between dose level 6 and 7. From Tables 1 and 2, it is obvious that the two-stage design requires many fewer patients at the dose levels lower than MTD. From Table 3, we can see a large gain in the expected sample size with TSER, i.e., 17 compared 26 in TER. On average, both methods cause two DLTs each, and five patients are treated above the MTD. The TSER increases slightly in precision compared to TER (66 vs. 70 in dispersion of simulated MTDs). In the given scenario, both TER and TSER underestimate the true MTD (about 13%). This bias can be reduced using the so-called continual reassessment method^[4,7] to be discussed next.

Table 1 Simulation Results from TER

Dose level	1	2	3	4	5	6	7
Dose	30	45	68	101	151	228	342
DLT rate (%)	1	1.2	1.5	2.2	3.7	8.4	25
Mean n	3.1	3.1	3.1	3.2	3.5	5.0	5.0
MTD rate (%)	0	0	1	2	6	57	33

CONTINUAL REASSESSMENT METHOD

The continual reassessment method (CRM)^[2,4,8] was initially developed for phase I oncology dose escalation trial. However, it can be used for many different trials. With CRM, the dose-response relationship is continually reassessed based on accumulative data collected from an ongoing trial. The next enrolled patient is then assigned to the current estimated MTD level. This approach is more efficient than that of the usual TER with respect to the allocation of the MTD; however, the efficiency of CRM could diminish when there are delayed responses and a constraint on dose jump in practice.^[2] In what follows, we will discuss computer simulation using CRM.

Dose-Toxicity Modeling

In most phase I dose-response trials, it is assumed that there is a monotonic relationship between dose and toxicity. This ideal relationship suggests that the biologically inactive dose is lower than the active dose, which is in turn lower than the toxic dose. To characterize this relationship, the choice of an appropriate dose-toxicity model is important. In practice, the logistic model is often utilized

$$p(x) = [1 + b \exp(-ax)]^{-1} \quad (1)$$

where $p(x)$ is the probability of toxicity associated with dose x , and a and b are positive parameters to be determined. Practically, $p(x)$ is equivalent to the toxicity rate or

DLT rate. Denote θ the probability of DLT (or DLT rate) at the MTD. Then, the MTD can be expressed as

$$\text{MTD} = \frac{1}{a} \ln \left(\frac{b\theta}{1-\theta} \right) \quad (2)$$

If we can estimate a and b or their posterior distributions (for the common logistic model, b is predetermined.), we will be able to determine the MTD from (2) or provide predictive probabilities for the MTD. The choice of the toxicity rate at the MTD, θ , depends on the nature of the DLT and the type of target tumor. For an aggressive tumor and a transient and non-life-threatening DLT, θ could be as high as 0.5. For persistent DLT and less-aggressive tumors, it could be as low as 0.1 to 0.25. A commonly used value is somewhere between 0 and $1/3 = 0.33$.^[3]

Reassessment of Model Parameters

The key is to estimate the parameter a in the response model [Eq. (1)]. An initial assumption or a prior distribution of the parameter is necessary to assign patients to the dose level based on the dose–toxicity relationship. This estimation of a is continually updated based on cumulative data observed from the trial. The estimation method can be a Bayesian or frequentist approach. The Bayesian approach leads to the posterior distribution of a . Frequentist approaches such as the maximum likelihood estimate or the least square estimate are straight forward. Note that the Bayesian approach requires specification of a prior distribution of parameter a . It provides posterior distribution of a and predictive probabilities of the MTD.

Prior Distribution of Parameter a

The Bayesian approach requires the specification of prior probability distribution of the unknown parameter a , i.e.,

$$a \sim g_0(a) \quad (3)$$

where $g_0(a)$ is the prior probability distribution.

Likelihood Function

The next step is to construct the likelihood function. Given n observations with y_i associated with dose x_{m_i} , the likelihood function can be written as

$$f_n(\mathbf{r} | a) = \prod_{i=1}^n [p(x_{m_i}, a)]^{r_i} [1 - p(x_{m_i}, a)]^{1-r_i} \quad (4)$$

where

$$r_i = \begin{cases} 1, & \text{if } y_i \geq \tau \\ 0, & \text{otherwise} \end{cases} \quad (5)$$

Assessment of Parameter a

The assessment of the parameters in the model can be carried out in different ways using Bayesian and frequentist approaches. The Bayesian approach assesses the posterior probability distribution of the parameter, while a frequentist approach provides a point estimate of the parameter.

Bayesian approach For the Bayesian approach, the posterior probability can be obtained as follows

$$g(a | \mathbf{r}) = \frac{f_n(\mathbf{r} | a)g_0(a)}{\int f_n(\mathbf{r} | a)g_0(a)da} \quad (6)$$

We then update the probabilities of the outcome or the predictive probabilities

$$p = \int p(\mathbf{x}, a)g(a | \mathbf{r})da \quad (7)$$

Maximum likelihood approach The maximum likelihood estimate of the parameter is given by

$$a_{\text{MLE}} = \arg \max_a \{f_n(\mathbf{r} | a)\} \quad (8)$$

where a_{MLE} is the parameter vector.

Least square approach The least square approach minimizes the difference between predictive probability and the observed rate or probability, which is given below.

$$a_{\text{LSE}} = \arg \min_a \{L_j(a)\} \quad (9)$$

where

$$L(a) = \sum_{i=1}^k (p(x_i, a) - \hat{p}(x_i, a))^2$$

Assignment of Next Patient

The updated dose–toxicity model is used to determine the dose level for the next patient. In other words, the next patient enrolled in the trial is assigned to the current estimated MTD based on the dose–response model. Practically, this assignment is subject to safety constraints such as a limited dose jump.

SIMULATION EXAMPLE USING CRM

We simulate the previous dose-escalation trial using the Bayesian continual reassessment method. The logistic model is used to model the dose–toxicity relationship, i.e., $\Pr(x = 1) = (1 + 150e^{-ax})^{-1}$ where parameter a follows an

Table 4 Simulation Results with CRM

Dose level	1	2	3	4	5	6	7
Dose	30	45	68	101	151	228	342
P_{DLT} (%)	1	1.2	1.5	2.2	3.7	8.4	25
$\hat{P}_{\text{DLT}}$ (%)	0.9	1.1	1.4	2.2	4.1	10.3	30
σ_{DLT} (%)	1	1	0.3	0.6	1.5	5.2	15
n	1	1	1	1	1.24	9.24	6.5

P_{DLT} , DLT rate, $\hat{P}_{\text{DLT}}$ and σ_{DLT} are the predicted rate and its standard deviation. n = number of patients.

uniform prior distribution over a range of [0, 0.3]. The next patient is assigned to the dose level that has the predicted response rate closest to the target DLT rate of 0.17 as defined earlier for the MTD. No response delay is considered. Owing to safety concerns, no dose jump is allowed. Ten thousand simulations were conducted using *ExpDesign Studio*® version 2.0, where 21 subjects were used for each trial or simulation. The results are summarized in Table 4.

In this example, the CRM produces excellent predictions for the DLT rates. We can see that one of the advantages with CRM is that it produces the posterior parameter distribution and predicted probability of DLT for each dose level (any dose) and allows us to select an unplanned dose level as the MTD. In the current case, the true MTD is 300 mg/m² with a DLT rate $P_{\text{DLT}} = 0.17$, which is an unplanned dose level. As long as the dose–response model is appropriately selected, bias can be avoided. This is an advantage compared to TER and TSER discussed earlier. The simulations also indicate that the number of DLTs per trial is 2.5. The number of patients treated with dose higher than MTD is 6.5 per trial. These numbers are larger than those in TER and TSER, which can be viewed as a trade-off with a reduction in bias.

CONCLUSIONS

Simulations have many applications in clinical trials. In early phases of the clinical development with many uncertainties (variables), CTS can be used to assess the impacts of the variables. CTS with the Bayesian approach could produce certain desirable operating characteristics that can answer questions raised in the early development phase such as posterior distribution of toxicity. There are a few things we should caution about with regard to CTS. The quality of simulation results is very much dependent

on the quality of the pseudorandom number. We should be aware that most built-in random number generators in computer languages and software tools are poor in quality; therefore it should not be used directly if we are not sure about the algorithm.

Implementing a high quality of random-number generator is as simple as a dozen of lines of computer code^[9, 10] as implemented by *ExpDesign Studio*. The common steps for conducting a CTS are defining the objectives, analyzing the problem, assessing the scope of the work and proposing time and resources required to complete the task, examining the assumptions, obtaining and validating the data source if applicable, nailing down evaluation criteria for various trial designs/scenarios, selecting an appropriate software tool, outlining the computer algorithms for the simulation, implementing and validating the algorithms, proposing scenarios to simulate, conducting simulations, interpreting results and making recommendations, and, last but not least, addressing the limitations of the performed simulations.

Clinical Trial Simulations: Later Development Phases

Mark Chang

Veristat, Southborough, Massachusetts, U.S.A.

Abstract

Clinical trial simulation plays an important role in drug development and, in recent years, it has become increasingly popular in the pharmaceutical industry. The focus of this entry is the simulation for adaptive trial designs, which will be defined in detail through several statistical examples.

INTRODUCTION

The traditional approach to drug development is a mixture of statistical and ad hoc methods. In many cases, assumptions are often introduced to simplify the problem and fit it into the statistics paradigm. In other cases, ad hoc decisions have to be made to deal with more complicated situations. Clinical trial simulation (CTS) with computers has been used for several decades.^[1] However, it was not until recent years that CTS started to play an important role in drug development and became increasingly popular in the pharmaceutical industry.^[2] Computer simulation can be used to model very complicated situations (virtually any situation that we can specify) with minimum assumptions. It can be used to search for an optimal trial design or clinical development plan. CTS can also be used to visualize the dynamic trial process from recruiting patients, distributing drugs, and conducting treatments to observing pharmacokinetic processes and clinical responses (efficacy and safety). Trial simulation can be combined with analytical approaches to improve the performance or efficiency of the simulation. For instance, a biotech company planned to launch a phase IIb early ACS (early glycoprotein IIb–IIIa inhibition in non-ST-segment elevation acute coronary syndrome) study. However, the pivotal studies used for approval were done more than six years ago. Since then, there have been noticeable changes in the patient population composition and medical technology. Concerns were raised. What is the likelihood of success for the trial? What would be the optimal design? What treatment effect would likely be seen? What would be the right population for the trial? A set of stringent patient inclusion/exclusion criteria may increase the probability of success, but it could also shrink the patient population to exclude patients who may have gained potential benefit from the drug. On the other hand, if we target a larger patient population by loosening the inclusion/exclusion criteria, the average effect of the drug would likely diminish and so would the probability of success. Facing these complex issues, the company decided to launch CTS to assist in the decision making.

First, a huge data source was identified from relevant trials conducted internationally over the past eight years. Then, analytical approaches, such as logistic regression, were used to search for sensitive variables (baseline and procedure variables) that are both clinically and statistically significant. As a result, a dozen sensitive variables were identified among nearly 40 potential candidates. Next, a stochastic model was introduced for computer simulations. Meanwhile, the data source was reconstructed as a training set and a test/validation set. Hundreds of simulations were conducted under various scenarios with different combinations of the sensitive variables. The simulations were able to provide the probability of trial success, distribution of the treatment effect, and the associated cost for each design scenario. The company made the decision to launch the large clinical trial with the assistance of the valuable information from the computer simulations. Further discussion of the whole spectrum of the simulations is beyond the scope of this section and will not be pursued here. Instead, in what follows, we will focus on the simulation for adaptive trial designs, which will be defined shortly. There are several reasons to choose adaptive design for the simulation topic: (1) adaptive design is very attractive to both practitioners and researchers;^[1,3–23] (2) the statistical theory of adaptive design is very complicated with very limited analytical solutions available under some strong assumptions, and it is unlikely that there will be sufficient analytical solutions for complicated adaptive designs in the near future; and (3) computer simulation of an adaptive design is straight forward and easy to implement.

OVERVIEW OF ADAPTIVE DESIGN

Drug development is a sequence of complicated decision-making processes. Options are provided at each stage, and decisions are dependent on the prior information and the probabilistic consequence of each action (decision). This requires the trial design to be flexible such that it can be modified during the trial process. Adaptive design emerges

Fig. 1 Overview of adaptive design

for this reasoning and has become very attractive in the pharmaceutical industry. Adaptive design refers to a design that allows adaptations or modifications to some aspects of the trial after its initiation without undermining the validity and integrity of the trial. The adaptations may include, but are not limited to: (1) early stopping due to efficacy or futility; (2) sample size reestimation; (3) dropping inferior treatment groups; (4) adding new treatment groups; (5) response-adaptive randomization; (6) modification of the target population; (7) study endpoint change; (8) hypothesis change; (9) treatment switching (crossover); and (10) any combination of the above adaptations. An adaptive design usually consists of two or more stages; at each stage, data analyses are conducted, and adaptations are made based on updated information to maximize the chance of success.

Although methods using the Brownian motion^[15] and Fisher's combination of independent p -values^[4,5] have been used in group-sequential and adaptive designs, because of great uncertainty surrounding source information, mechanism of action, treatment effect and its variability, interaction with environment, etc., using a traditional mathematical or statistical approach makes it difficult to model the dynamic system of trials. CTS is a powerful tool for achieving the optimal design. An overall process of an adaptive design is depicted in Fig. 1.

UTILITY-BASED TRIAL OBJECTIVE

A clinical trial typically involves multiple endpoints such as efficacy, safety, and cost. Therefore, a single measure, i.e., utility index, that summarizes the effects of major endpoints is desirable. The trial objective then becomes to find the dose or treatment with the maximum response probability (rate). The response probability is defined as $\Pr(u \geq c)$, where u is the utility index and c is a threshold. The utility index is the weighted average of trial endpoints such as safety and efficacy. The weights and the threshold are often determined by experts in the relevant field.

Fig. 2 Hyperlogistic function

DOSE-RESPONSE MODEL

The response of an ongoing trial can be modeled using a function. We find that the following so-called hyperlogistic function can be used to model many different response shapes (Fig. 2). The hyperlogistic function is defined by the probability of response

$$\Pr(x=1) = (a_1 \exp(a_2 x) + a_3 \exp(-a_4 x))^{-a_5}$$

The modeling can be on a continual basis, i.e., the model is updated when new response data become available. This approach refers to the continual reassessment method (CRM), which can be either a Bayesian- or frequentist-based method. If the observed responses are used as the basis for an adaptation instead of modeled or predicted response, we call it a null-model approach.

ADAPTATION RULES

Randomization Rules

It is desirable to randomize more patients to superior treatment groups. This can be accomplished by increasing

the probability of assigning a patient to the treatment group when the evidence of responsive rate increases in a group. The response-adaptive randomization rule can be the randomized-play-the-winner or Utility-offset model (UOM).

Response-adaptive randomization requires unblinding the data, which may not be feasible at real time. There is often a delayed response, i.e., randomizing the next patient before knowing responses of previous patients. Therefore, it is practical to unblind the data several times during the trial, i.e., group sequential response-adaptive randomization, instead of fully sequential adaptive randomization.

Early Stopping Rules

It is desirable to stop a trial when the efficacy or futility of the test drug becomes obvious during the trial. To stop a trial prematurely, we provide a threshold for the number of subjects randomized and at least one of the following:

1. *Utility rules:* The difference in response rate between the most responsive group and the control group exceeds a threshold, and the corresponding two-sided 95% naive confidence interval lower bound exceeds a threshold.
2. *Futility rules:* The difference in response rate between the most responsive group and the control is lower than a threshold, and the corresponding two-sided 90% naive confidence interval upper bound is lower a threshold.

Rules for Dropping Losers

In addition to the response-adaptive randomization, you can also improve the efficiency of a trial design by dropping some inferior groups (losers) during the trial. To drop a loser, we provide two thresholds for: (1) maximum difference in response rate between any two dose levels and (2) the corresponding two-sided 90% naive confidence lower bound. We may choose to retain all the treatment groups without dropping a loser and/or to retain the control group with a certain randomization rate for the purpose of statistical comparisons between the active groups and the control.

Sample Size Adjustment

Sample size determination requires anticipation of the expected treatment effect size defined as the expected treatment difference divided by its standard deviation. It is not uncommon that the initial estimation of the effect size turns out to be too large or small, which consequently leads to an underpowered or overpowered trial. Therefore,

it is desirable to adjust the sample size according to the effect size for an ongoing trial.

The sample size adjustment is determined by a power function of treatment effect size, i.e.,

$$N = N_0 \left(\frac{E_{0\max}}{E_{\max}} \right)^a \quad (1)$$

where N is the newly estimated sample size, N_0 , the initial sample size, and a is a constant. The effect size $E_{\max}$ is defined as

$$E_{\max} = \frac{p_{\max} - p_1}{\sigma^2}; \quad \sigma^2 = \bar{p}(1 - \bar{p});$$

$$\bar{p} = \frac{p_{\max} + p_1}{2}$$

$p_{\max}$ and p_1 are the maximum response rates and the control response rate, respectively, and $E_{0\max}$ is the initial estimation of $E_{\max}$.

RESPONSE-ADAPTIVE RANDOMIZATIONS

Conventional randomization refers to any randomization procedure with a constant treatment allocation probability such as simple randomization. Unlike the conventional randomization, response-adaptive randomization is a randomization in which the probability of allocating a patient to a treatment group is based on the response of the previous patients. The purpose is to improve the overall response rate in the trial. There are many different algorithms such as random-play-the-winner (RPW) (Fig. 3), the UOM and the maximum utility model (MUM).

RPW

The generalized RPW denoted by $\text{RPW}(n_1, n_2, \dots, n_k; m_1, m_2, \dots, m_k)$ can be described as follows:

1. Place n_i balls of the i th color (corresponding to the i th treatment) into an urn ($i = 1, 2, \dots, k$), where k is the number of treatment groups. There are initially $N = \sum n_i$ balls in the urn.
2. Randomly choose a ball from the urn. If it is the i th color, assign the next patient to the i th treatment group.
3. Add m_k balls of the i th color to the urn for each response observed in the i th treatment. This creates more chances for choosing the i th treatment.
4. Repeat steps 2) and 3).

When $n_i = n$ and $m_i = m$ for all i , we simply write $\text{RPW}(n, m)$ for $\text{RPW}(n_1, n_2, \dots, n_k; m_1, m_2, \dots, m_k)$.

Fig. 3 Random-play-the-winner

UOM

To have a high probability of achieving target patient distribution among the treatment groups, the probability of assigning a patient to a group should be proportional to the corresponding predicted or observed response rate minus the proportion of patients that have been assigned to the group, i.e.,

$$\Pr(i) = \begin{cases} \frac{1}{k}, & S_R = 0 \\ \frac{1}{c} \max \left\{ 0, \left(\frac{R_i}{S_R} - \frac{n_i}{N} \right) \right\}, & S_R > 0 \end{cases} \quad (2)$$

where the normalization factor $c = \sum_i \left(\frac{R_i}{S_R} - \frac{n_i}{N} \right)$, n_i is the number of patients that have been randomized to the i th group, R_i = the observed response rate for the i th group, $S_R = \sum_{i=1}^k R_i$, k = the number of dose groups, and N = the total estimated number of patients in the trial.

MUM

The MUM for the adaptive randomization always assigns the next patient to the group that has the highest response rate based on current estimation of either the observed or model-based predicted response rate.

NULL MODEL VS. MODEL APPROACH

It is interesting to compare model and null-model approaches. When the sample size is larger than 20 per group, there is no obvious advantage of using the model-based method with respect to the precision and accuracy (Table 1). Therefore, a null-model approach will be used in the subsequent simulations.

Table 1 Comparisons of Simulations Results

Dose level	1	2	3	4	5
Target rate	0.02	0.07	0.37	0.73	0.52
Simulated rate	0.02	0.07	0.36	0.73	0.52
Predicted rate	0.02	0.07	0.40	0.65	0.41
Standard deviation	0.00	0.02	0.11	0.09	0.04
Number of subjects	1.02	2.48	12.6	20.5	13.4
Simulated rate	0.02	0.05	0.36	0.73	0.51
Predicted rate	0.02	0.07	0.40	0.63	0.40
Standard deviation	0.00	0.02	0.13	0.11	0.05
Number of subjects	1.00	1.62	7.50	11.9	8.00
Simulated rate	0.02	0.06	0.34	0.72	0.51
Predicted rate	0.02	0.07	0.37	0.58	0.38
Standard deviation	0.00	0.02	0.15	0.14	0.06
Number of subjects	1.00	1.03	4.68	7.60	5.68

TEST STATISTIC

It is very interesting to know that the choice of test statistics for hypothesis tests is very flexible if the analysis is carried out through computer simulations. The only requirement is that the test statistic should be a monotonic function of both the treatment effect δ and the sample size n , which can be, for example, $\sqrt{n}\delta$ the treatment difference or the effect size $\sqrt{n}\delta/\sigma$, where σ is the standard deviation of δ . Using computer simulation, it is easy to generate the distributions of the test statistic under the null hypothesis and alternative hypothesis or any other specified conditions for monitoring purposes.

α -ADJUSTMENT

The α -adjustment is required when: (1) there are multiple comparisons with more than two groups involved; (2) there

Table 2 α Inflation/Deflation

Randomization	Inflated FWE α	Adjusted α
RPW(1,0)	0.146	0.015
RPW(1,1)	0.143	0.007

Note: Five group with total $N = 100$. H_0 rate = 0.5.

are interim looks, i.e., early stopping for futility or efficacy; and (3) there is a response-dependent sampling procedure such as response-adaptive randomization and unblinded sample size reestimation. When samples or observations from the trial are not independent, the response data are no longer normally distributed. Therefore, the p -value from a normal distribution assumption should be adjusted, or equivalently the α should be adjusted if the p -value is not adjusted (Table 2). For the same reason, the other statistic estimates from normal assumption should also be adjusted.

The adjusted α can be found easily using simulation. Run simulations under the null hypothesis H_0 to find the adjusted α for the pairwise comparisons such that familywise error rate = 0.025. Then run simulations under the alternative hypothesis H_a using the adjusted α to find the power for various sample sizes and other scenarios.

BIAS DUE TO ADAPTIVE RANDOMIZATION RPW(1,1)

The commonly used estimators that are based on the assumption of independent samples are often biased in the case of adaptive design (Table 3).

SIMULATION EXAMPLES

To investigate the effect of the adaptations, we will compare the classic, group sequential, and adaptive designs with regard to their operating characteristics using computer simulations. In what follows, each example represents a different trial design.

Examples 1 through 5 will use the following scenario: Assume a phase II oncology trial with two treatment groups. The primary endpoint is tumor response

Table 3 Bias in Rate Due to Adaptive Randomization

Dose level	1	2	3	4	5
Target rate	0.5	0.1	0.2	0.7	0.55
Number of patients	130	14	23	362	171
Observed rate	0.47	0.08	0.16	0.7	0.53
Standard deviation	0.10	0.08	0.10	0.05	0.08
Bias in rate	0.03	0.02	0.04	0.00	0.02

$N = 700$; 100,000 simulations.

(PR and CR) and the estimated response rates for the two groups are 0.2 and 0.3, respectively. We use simulation to calculate the sample size required, given that one-sided $\alpha = 0.05$ and power = 80%.

Example 1: Conventional Design with Two Parallel Treatment Groups

A classic fixed sample size design with 600 subjects will have a power of 81.4% at one-sided $\alpha = 0.025$. The total number of responses per trial is 150 based on 10,000 simulations.

Example 2: Flexible Design with Sample Size Reestimation

The power of a trial is heavily dependent on the estimated effect size; therefore it is desirable to have a design that allows modification of the sample size at some point during the trial. Let us redesign the trial in Example 1 such that it allows a sample size reestimation and then study the robustness of the design.

To control the FWE at 0.025, the α must be adjusted to 0.023 which can be done by computer simulation under the null hypothesis. The average sample size is 960 under the null hypothesis. Using the algorithm for sample size reestimation (1), where $E_{0\max} = 0.1633$ and $a = 2$, the design has 92% power with an average sample size of 821.5.

Now assume that the initial effect sizes are not 0.2 vs. 0.3 for the two treatment groups. Instead, they are 0.2 and 0.28, respectively. We want to know what the power of the flexible design will have. Keep everything the same (also keep $E_{0\max}$ to be 0.1633), but change the response rates to 0.2 and 0.28 for the two dose levels and run the simulation again. It turns out that the design has 79.4% power with an average sample size of 855.

Given the two response rates 0.2 and 0.28, the design with a fixed sample size of 880 has a power of 79.4%. We can see that there is a saving of 25 patients by using the flexible design. If the response rates are 0.2 and 0.3, for 92.1% power, the required sample size is 828 with the fixed sample size design, which means that the flexible design saves six to seven subjects. A flexible design increases power when observed effect size is less than expected, while a traditional design with a fixed sample size either increases or decreases the power regardless of the observed effect size when the sample increases.

Example 3: Design with RPW Randomization

To randomize more patients to the superior treatment group using response-adaptive randomization, the same example with a sample size of 600 subjects is used. The commonly used response-adaptive randomization is RPW(1, 1), i.e., one initial ball for each group and one additional ball with the corresponding color for each response. The data will

Table 4 Group Sequential Design

Dose level	Control	Active
Number of patients	244	244
Response rate	0.2	0.3
Observed rate	0.198	0.303
Standard deviation	0.028	0.033

be unblinded for every 100 new patients. The adjusted α is found to be 0.02. The design has 77.3% power with an average sample size of 600. On average, there are 223 subjects in dose level 1 and 377 in dose level 2. The expected number of responses is 158. Comparing this to the classic design in Example 1, the RPW design gains eight responses but loses 4% power.

Example 4: Group Sequential Design with One Interim Analysis

Group sequential design is very popular in clinical trials. For the two arm trial, the adjusted α is found to be 0.024. The maximum number of subjects is 700. The trial will stop if 350 or more patients are randomized, and one of the following criteria is met: 1) The efficacy (utility) stopping criterion: The maximum difference in response rate between any dose and the control is larger than 0.1 with the lower bound of the two-sided 95% naive confidence interval greater than or equal to 0.0 or 2) The futility stopping criterion: The maximum difference in response rate between any dose and dose level 1 is less than 0.05 with the upper bound of the one-sided 95% naive confidence interval less than 0.1 (Table 4).

The average total number of subjects for each trial is 488. The total number of responses per trial is 122. The probability of correctly predicting the most responsive dose level is 0.988 based on observed rates. Under the alternative hypothesis, the probability of early stopping for efficacy is 0.505, and the probability of early stopping for futility is 0.104. The power for testing the treatment difference is 0.825.

Example 5: Adaptive Design Permitting Early Stopping and Sample Size Reestimation

Sometimes it is desirable to have a design permitting both early stopping and sample size modification (Table 5).

With an initial sample size of 700 subjects, a grouping size of 350, and a maximum sample size of 1000, the one-sided adjusted α is found to be 0.05. The simulation results are presented as follows:

The maximum sample size is 700. The trial will stop if 350 patients or more are randomized, and one of the following criteria is met: (1) the efficacy (utility) stopping criterion: the maximum difference in response rate between

Table 5 Design with Early Stopping and n -Reestimation

Dose level	Control	Active
Number of patients	271	272
Response rate	0.2	0.3
Observed rate	0.198	0.303
Standard deviation	0.028	0.032

any dose and the control is larger than 0.1 with the lower bound of the two-sided 95% naive confidence interval greater than or equal to 0.0 or (2) the futility stopping criterion: the maximum difference in response rate between any dose and the control is less than 0.05 with the upper bound of the one-sided 95% naive confidence interval less than 0.1. The sample size will be reestimated when 350 subjects have been randomized.

When the null hypothesis is true ($p_1 = p_2 = 0.2$), the average total number of subjects for each trial is 398.8. The probability of early stopping for efficacy is 0.0096. The probability of early stopping for futility is 0.9638.

When the alternative hypothesis is true ($p_1 = 0.2$, $p_2 = 0.3$), the average total number of subjects for each trial is 543.5. The total number of responses per trial is 136. The probability of correctly predicting the most responsive dose level is 0.985 based on observed rates. The probability of early stopping for efficacy is 0.6225. The probability of early stopping for futility is 0.1546. The power for testing the treatment difference is 0.842.

Examples 6 through 8 are for the same scenario as the six arm study with response rates of 0.5, 0.4, 0.5, 0.6, 0.7, and 0.55 for the six dose levels from doses 1 through 6, respectively.

Example 6: Conventional Design with Multiple Treatment Groups

With 800 subjects, a 0.5 response rate under H_0 , and a grouping size of 100, we found the one-sided adjusted α to be 0.0055. The total number of responses per trial is 433. The probability of correctly predicting the most responsive dose level is 0.951 based on observed rates. The power for testing the maximum effect comparing any dose level to the control is 80%. The powers for comparing each of the five dose levels to the control are 0, 0.008, 0.2, 0.796, and 0.048, respectively.

Example 7: Response-Adaptive Design with Multiple Treatment Groups

To further investigate the effect of RPW randomization RPW(1, 1), a design with 800 subjects, a grouping size of 100, and a response rate of 0.2 under the null hypothesis are simulated. The one-sided adjusted α is found to be 0.016. Using this adjusted α and response rates 0.5, 0.4, 0.5,

Table 6 Design with RPW(1, 1) Under H_0

Dose level	1	2	3	4	5	6
Response rate	0.5	0.5	0.5	0.5	0.5	0.5
Observed rate	0.50	0.49	0.49	0.49	0.49	0.49

Table 7 Design with RPW(1, 1) Under H_a

Dose level	1	2	3	4	5	6
Number of subjects	200	74	100	133	176	116
Response rate	0.5	0.4	0.5	0.6	0.7	0.55
Observed rate	0.50	0.39	0.49	0.59	0.7	0.54

0.6, 0.7, and 0.55 for dose levels 1 through 6, respectively, the simulation indicates that the designed trial has 86% power and 447 responders per trial on average. In comparison to 80% power and 433 responders for the design with simple randomization RPW(1, 0), the adaptive randomization is superior in both power and number of responders. The simulation results also indicate that there are biases in the estimated mean response rates in all dose levels except dose level 1, where a fixed randomization rate is used (Tables 6 and 7).

The average total number of subjects for each trial is 800. The total number of responses per trial is 446.8. The probability of correctly predicting the most responsive dose level is 0.957 based on observed rates. The power for testing the maximum effect comparing any dose level to the control (dose level 1) is 0.861 at a one-sided significance level (α) of 0.016. The powers for comparing each of the five dose levels to the control are 0, 0.008, 0.201, 0.853, and 0.051, respectively.

Example 8: Adaptive Design with Dropping Losers

Implementing the mechanism of dropping losers can also improve the efficiency of a design. With 800 subjects, a grouping size of 100, a response rate of 0.2 under the null hypothesis, and a fixed randomization rate in dose level 1 at 0.25, an inferior group (loser) will be dropped if the maximum difference in response between the most effective group and the least effective group (loser) is greater than 0 with the lower bound of the one-sided 95% naive confidence interval greater than or equal to 0. Using the simulation, the adjusted α is found to be 0.079. From the simulation results below, more biases can be observed with this design. The design has 90% power with 467 responders. The probability of correctly predicting the most responsive dose level is 0.965 based on observed rates. The powers for comparing each of the five dose levels to the control (dose level 1) are 0.001, 0.007, 0.205, 0.889, and 0.045, respectively. The design is superior to both RPW(1, 0) and RPW(1, 1) (Tables 8 and 9).

Table 8 Bias in Rate with Dropping Losers Under H_0

Dose level	1	2	3	4	5	6
Response rate	0.5	0.5	0.5	0.5	0.5	0.5
Observed rate	0.50	0.46	0.46	0.46	0.46	0.46

Table 9 Bias in Rate with Dropping Losers Under H_a

Dose level	1	2	3	4	5	6
Number of subjects	200	26	68	172	240	95
Response rate	0.5	0.4	0.5	0.6	0.7	0.55
Observed rate	0.50	0.37	0.46	0.57	0.69	0.51

Example 9: Dose Response Trial Design

The trial objective is to find the optimal dose with the highest response rate. There are five dose levels and 30 planned subjects in each simulation. The hyperlogistic model is defined with the parameters $a_3 \in [20, 100]$ and $a_4 \in [0, 0.05]$. The RPW(1, 1) is used for the randomization. The simulation results show that the probability of correctly predicting the most responsive dose level is 0.992 by the model and only 0.505 based on observed rates (Table 10).

DISCUSSION OF SIMULATION RESULTS

From classic design to group sequential design to adaptive design, each step forward increases in complexity and at the same time improves the efficiency of clinical trials as a whole. Adaptive designs can increase the number of responses in a trial and provide more benefits to the patient in comparison to the classic design. With sample size reestimation, an adaptive design can preserve the power even when the initial estimations of treatment effect and its variability are inaccurate. In the case of a multiple-arm trial, dropping inferior arms or response-adaptive randomization can improve the efficiency of a design dramatically. Finding analytic solutions for adaptive designs is theoretically challenging. However, computer simulation makes it easier to achieve an optimal adaptive design. It allows a wide range of test statistics as long as they are monotonic functions of treatment effects. Adjusted α s and

Table 10 Dose Response Trial Design

Dose level	1	2	3	4	5
Number of subjects	15	30	50	85	110
Response rate	0.2	0.3	0.6	0.7	0.5
Observed rate	0.193	0.294	0.593	0.691	0.489
Predicted Rate	0.098	0.181	0.406	0.802	0.379
σ_{obs}	0.185	0.209	0.221	0.204	0.226
σ_{prd}	0.074	0.073	0.104	0.151	0.056

p -values because of response-adaptive randomization and other adaptations with multiple comparisons can be determined easily using computer simulations. Unbias in point estimations with adaptive designs has not been completely resolved yet using computer simulations. However, the bias can be ignored in practice by using a proper grouping size (cluster) such that there are only a limited number of adaptations (<8).

CONCLUSIONS

We have demonstrated that CTS can be used for various complex designs. By comparing the operating characteristics of each design provided by CTS, we are able to choose an optimal design or development strategy. Computer simulation is commonly seen in statistics literature related to clinical trials, most of them for power calculations and data analyses. We will see more pharmaceutical companies using CTS for their clinical development planning to streamline the drug process, increase the probability of success, and reduce the cost and time-to-market. Ultimately, CTS will bring the best treatment to the patients. When conducting CTS for an adaptive design, the following is recommended to protect the integrity of the trial: Specify in the trial protocol: (1) the type of adaptive design; (2) details of the adaptations to be used; (3) the estimator for treatment effect; and (4) the hypotheses and the test statistics. Run the simulation under the null hypothesis and construct the distribution of the test statistic. To estimate the sample size for the adaptive design, run the simulation under the alternative hypothesis and construct the distribution of the test statistic. Sensitivity analyses are suggested to simulate potential major protocol deviations that would impact the validity of the trial simulations. To achieve an optimal design, a Bayesian or frequentist–Bayesian hybrid adaptive approach should be used. There are several simulation tools available on the web. For adaptive designs discussed in this section ExpDesign Studio® can be used.

Clinical Trial: Combination Drug Development

H. M. James Hung

Division of Biometrics I, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Abstract

Combination treatments are widely used in medicine. This entry discusses the many interesting yet difficult statistical design and inference problems in regards to combination treatment trials.

Keywords: Combination dose; Combination treatment; Fixed dose.

INTRODUCTION

Combination treatments are widely used in medicine. The U.S. Food and Drug Administration's general policy regarding fixed-dose, combination-dosage form prescription drugs for humans is that two or more drugs may be combined in a single-dosage form when each component makes a contribution to the claimed effects of the combination and the dosage of each component is such that the combination is safe and effective for a significant patient population requiring such concurrent therapy as defined in the labeling for the drug [21 CFR 300.50]. As described in Ref. [1], this general rule could be interpreted in several distinct contexts between the notion of contributing in the strict sense of superiority and the notion of additivity, synergy, and antagonism that scientists in the fields of pharmacology and toxicology have long considered. In clinical studies, the most prevalent interpretation of the rule is that the combination is superior to its components in terms of effectiveness or safety. The relationship between these notions has been explored by Laska et al.^[1]

In many diseases, for example, hypertension, drug treatments for the patients are administered according to a dose titration schedule. Dose-effect information is essential for drug labeling, particularly if one or both of the component drugs have dose-dependent side effects. Therefore, a multilevel factorial design trial for simultaneously studying multiple-dose combinations is often asked for during the development of combination drugs, as articulated in Refs. [2] and [3]. Such a factorial design trial is also needed for studying a combination drug proposed for use as an initial therapy.

STATISTICAL DESIGNS AND ANALYSIS METHODS

Fixed-Dose Combination

The clinical trial design for evaluation of a fixed-dose combination from two drugs is usually a full two-by-two

factorial design that exposes the four combinations composed from placebo and the specified dose for one drug and placebo and the specified dose for the other, as illustrated in the following layout.

P	B
A	AB

Here P labels the placebo-placebo combination, A is the combination of Drug A and the placebo of Drug B, B is the combination of Drug B and the placebo of Drug A, and AB is the combination of Drug A and Drug B. The placebo-placebo combination may sometimes be voided but usually it is preferred to include this combination, at least, for the purpose of checking the activity of each component drug. The subjects enrolled are randomly allocated into the three or four combination cells. The allocation can be in equal or unequal proportion.

The primary statistical hypothesis of concern involves two pairwise comparisons between the combination and the two components. Both of the comparisons must succeed in order to prove the notion of contributing. This is a well-known statistical testing problem studied in the literature.^[4,5] A natural joint test is the so-called min test^[6] that is generated by taking the minimum of the individual standardized tests for the respective pairwise comparisons. In parametric testing, such as testing for mean difference, the distribution of the min test involves a primary parameter and a nuisance parameter. The primary parameter is the minimum of the values of the parameters for the two respective comparisons. The nuisance is the difference of the values of the parameters for the two comparisons. If the hypothesis pertains to a single response, then the primary parameter measures the least gain of effect by use of the combination relative to its components whereas the nuisance is the mean difference of the components.

Snapinn^[7] constructed five tests based on the min test. Each of his first four tests ($T_1 - T_4$) employs a different estimate of the nuisance parameter that is derived from

the same set of the data used for testing the hypothesis of the primary parameter. As reported by Snapinn^[7] and Hung et al.,^[3] the tests could be biased in favor of the combination treatment. That is, if the true value of the nuisance parameter differs from the estimate, then the tests could lead one to falsely assert that the combination is superior to the components more often than it should. The maximum Type I error probability for each of these tests exceeds the target α level. Snapinn's fifth test (T_5) is the α -level min test, later presented by Laska and Meisner,^[6] which requires the individual test statistics to reject the respective null hypotheses at the level of at most α . Equivalently, the individual p values for all pairwise comparisons must not exceed α . The α -level min test has existed early in the literature,^[4] and its maximum Type I error probability is α . Laska and Meisner^[6] showed an optimality property of this test, the implication of which needs to be an important consideration in regulatory applications. The performance of the α -level min test as a function of the nuisance parameter was further explored in Refs. [3,8–10]. Others (e.g., Refs. [11–13]) also contemplated the possibility of improving the min test. It is clear that the α -level min test cannot be improved unless the true value of the nuisance parameter is known to be in a very narrow range or under a specific alternative.

The statistical power of the α -level min test depends on the primary parameter and the nuisance parameter discussed above. In case of testing a mean parameter, given any fixed value of the primary parameter, the power of the α -level min test increases as a function of the absolute value of the nuisance parameter. Therefore, given any value of the primary parameter, the α -level min test has the smallest power when the nuisance parameter is null. Ideally, the sample size for a fixed-dose combination trial should be planned to ensure a sufficient power for detecting an expected value of the primary parameter, assuming that the nuisance parameter is zero, i.e., the two components have an identical effect.

The problem of comparing a combination treatment with its component drugs on multiple-response variables has been extensively studied in Ref. [14]. The multivariate responses present more than one way of interpreting “making a contribution” depending on the claimed effects. The optimality of the α -level min test in the univariate response case also carries to the multiple-response case for showing that the combination is superior to the components on all response variables.

MULTIPLE-DOSE COMBINATIONS

A multilevel factorial design is a natural choice for studying multiple-dose combinations of two drugs simultaneously in one trial. A factorial design layout is illustrated as follows:

$$\begin{array}{ccccccc} A_0 B_0 & A_0 B_1 & A_0 B_2 & \dots & A_0 B_s \\ A_1 B_0 & A_1 B_1 & A_1 B_2 & \dots & A_1 B_s \\ A_2 B_0 & A_2 B_1 & A_2 B_2 & \dots & A_2 B_s \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ A_r B_0 & A_r B_1 & A_r B_2 & \dots & A_r B_s \end{array}$$

Here in the $(r+1) \times (s+1)$ factorial layout, $A_i B_j$ labels the combination of the i th dose of Drug A and the j th dose of Drug B, and A_0 and B_0 are the placebos of Drug A and Drug B, respectively. The subjects enrolled are randomly allocated to the cells. As articulated in Refs. [2] and [3], such a factorial design trial carries multiple objectives. For one, the study needs to provide confirmatory evidence for the assertion that the combination of the drugs is more beneficial than each component drug alone. Another objective is to obtain reliable and useful dose-effect information for writing instruction for use in drug labeling.

The definition for superiority of the combination drug over the component drugs in studying multiple-dose combination is not obvious. Hung et al.^[2] presented two distinct concepts of global superiority. In a weak sense of global superiority, the average of all the nonzero dose combinations is superior to both of the averages of the individual component doses. In a strong sense, there exist some nonzero dose combinations that are superior to the respective components in the dose region under study. The weak sense is less desirable because by showing it there is no guarantee that there is a single-dose combination superior to its components.

To demonstrate the strong sense of global superiority, the classical analysis of variance (ANOVA) using the additive model (i.e., no drug by drug interaction terms) can be a very powerful method. The additive model prescribes that the effect of each nonzero dose combination is the sum of the effects of its components. If the true effect of a dose combination is less than the sum of the component effects, the additive model will overestimate the effect of the combination. For such dose combinations, the probability of falsely asserting superiority over the components will be greater than it should. Thus, the assumption of no drug interaction is essential to the validity of the ANOVA using the additive model. The classical global F test for testing additivity does not guarantee that nonadditivity is always detectable at each dose combination. The patterns depicted by the estimates of the drug by drug interactions for the dose combinations may be more informative for detecting the possible presence of nonadditivity at the local level.

When the validity of the ANOVA is in doubt, some alternative useful methods for testing the strong-sense global superiority are α -level AVE and MAX tests developed by Hung et al.^[15] These global tests are based on the estimate of the least gain in effect resulting from use of each combination relative to its component. The AVE

test is an average of the min test statistics applied to the nonzero dose combinations under study whereas the MAX test takes the largest min test statistic. The α -level AVE test imposes a weak control on the familywise Type I error probability; that is, the probability of the Type I error associated with the global null hypothesis that none of the dose combinations under study are superior to their respective components is maintained at α . The α -level MAX test controls at the maximum probability of the familywise Type I error incurring in the pairwise comparisons between all nonzero dose combinations and their respective components (i.e., strong control). These tests have been extended to the incomplete factorial designs where some nonzero dose combinations are not studied and to the unbalanced designs where the cell sample sizes are not equal (see Refs. [16] and [17]).

The power functions of both the α -level AVE test and the α -level MAX test contain the nuisance parameters, each quantifying the difference of the respective component doses. The most conservative but perhaps impractical strategy of sample size planning for a multifactorial trial is one that assumes an identical effect for each dose level of both component drugs. A practical strategy should rely on Monte Carlo simulation studies based on a number of layouts for possible expected effect sizes at all local cells.

A more informative approach is to identify a dose combination that is superior to the highest dose of Drug A and the highest dose of Drug B under study. The most natural dose combination for testing is the combination of the highest doses of Drug A and Drug B. In general, the α -level min test as described above is the test method to use. Some other considerations may lead to testing some lower dose combinations against the highest dose of each single drug alone. Strong control of type I error rate associated with testing such multiple dose combinations is generally required to assert which dose combination(s) is superior to the highest dose of either drug.

Dose-effect relationship can be studied using a biological model or an empirical statistical model, such as a quadratic polynomial model via response surface or regression analyses. The surface can provide valuable information as to whether the effect increases as a function of dose, whether the effect increases start to level off at some dose combination, or whether there may be drug by drug interactions. If the response surface model fits the dose-effect data well, then one can construct confidence surfaces to identify desirable dose combinations that have greater effects than the individual components with a desired level of confidence.^[18] Other useful analysis approaches using response surface method can be found in Ref. [19].

THERAPEUTIC SYNERGISM

The concept of therapeutic synergism proposed by Vennitti et al.^[20] and discussed further by Mantel^[21] can be

useful in characterizing the activities of a combination drug in factorial design clinical trials. This concept has been extensively employed in preclinical research on combination cancer therapies. Literature is abundant, such as an early review paper by Carter and Wampler,^[23] for this type of applications. Carter et al.^[22] stated that therapeutic synergism is said to exist if a combination treatment provides improved therapy as compared to the best-component single-drug therapy. As stipulated in Ref. [23], with response surface methodology, the location of optimum dose combination that gives the maximal effect in the study dose range can be estimated and a confidence region around the estimated dose combination can be calculated. If the confidence region excludes a zero dose of each drug in the combination, then therapeutic synergism is established. This method can be used to identify nonzero dose combinations as potential candidates for an initial therapy.

CONCLUSION

Combination treatment trials present many interesting yet difficult statistical design and inference problems. For testing a single dose combination versus its components, it is a typical intersection-union testing problem that involves the difference between the effects of the two components as the nuisance or ancillary parameter. Without a complete knowledge of the value of this parameter, the α -level min test described above is the only solution to the testing problem. From a design perspective, a good sample size plan should ensure that this test has sufficient statistical power under the worst scenario that the effects of the two component drugs are equal.

The multi-level factorial design provides a viable avenue for studying multiple dose combinations with multiple objectives entertained above. Depending on the study objective, sample size planning requires careful attention. If the objective is to assert that at least one dose combination is superior to its respective components, then the sample sizes need to be carefully allocated to all dose combination cells under testing. If, however, the objective is to identify which dose combination(s) is superior to the highest dose of each drug, then the tested dose combinations need to be loaded with the major portion of the total sample size. Multiple comparison adjustments need to be incorporated in sample size planning. Consequently, the dose-response exploration which involves other dose combinations will be based on much smaller sample sizes.

Clinical Trial: Failure-Time Model

Chin-Shang Li

St. Jude Children's Research Hospital, Memphis, Tennessee, U.S.A.

Abstract

In many clinical follow-up studies, the primary endpoint is the time to some event of interest, e.g., time from initial treatment to local recurrence of tumor. This type of event is generally referred to as a “failure.” This entry provides a brief overview of the model and discusses estimation models.

INTRODUCTION

In many clinical follow-up studies, the primary endpoint is the time to some event of interest, e.g., time from initial treatment to local recurrence of tumor. Such events are generically called *failures*. The interval of interest, referred to as *failure time*, *survival time*, or *event time*, is often subject to right censoring, a form of incomplete observation in which the event of interest has not yet occurred. Other forms of censoring include left censoring and interval censoring. In left censoring, some observed times are greater than or equal to the actual failure times. Interval censoring means that some failures are known only to have occurred within some time interval.

One can describe the probability distribution of the failure time of an individual from a homogeneous population (i.e., no explanatory variables) in three ways: the survival function, the hazard function, and the probability density function. The survival and hazard functions are of particular interest in summarizing failure time data. Parametric models for failure time for a homogeneous population include the Weibull, gamma, log-normal, and log-logistic distributions. Nonparametric methods of estimating the survival function include Kaplan–Meier (product–limit) and Nelson–Aalen estimators. However, in follow-up trials, the failure times of individuals usually depend on characteristics that are also referred to as explanatory variables, covariates, or predictor variables. The explanatory variables may include demographic variables such as age, gender, and race, physiological variables such as weight, height, and blood pressure, and behavioral factors such as smoking history and dietary habits. The proportional hazards, accelerated failure time, and—proportional odds models can be used to model the hazard function, to determine which explanatory variables affect the hazard function, and to estimate the hazard function for an individual.

OVERVIEW

Let $T \geq 0$ be a random variable representing the failure time of an individual in a homogeneous population. The survival function is defined to be the probability that the failure time T is greater than or equal to time t , i.e., $S(t) = \Pr(T \geq t)$. The hazard function $h(t)$, expressing the risk or hazard of failure at time t given that failure has not occurred before time t , is expressed as

$$h(t) = \lim_{\Delta t \rightarrow 0^+} \frac{\Pr(T < t + \Delta t \mid t \leq T)}{\Delta t} = \frac{f(t)}{S(t)}$$

where $f(t) = \lim_{\Delta t \rightarrow 0^+} \Pr(t \leq T < t + \Delta t) = \Delta t = -dS(t)/dt$ is the probability density function of T . The hazard function is also called the *hazard rate*, the *instantaneous death rate*, the *intensity rate*, or the *force of mortality*. The survival function may be written as $S(t) = \exp(-H(t))$, where $H(t) = \int_0^t h(u)du$ is called an *integrated* or *cumulative hazard function*.

If the failure time T is assumed to have a Weibull distribution with scale parameter $\lambda > 0$ and shape parameter $\gamma > 0$, the survival and hazard functions are $S(t) = \exp(-\lambda t^\gamma)$ and $h(t) = \lambda \gamma t^{\gamma-1}$, which is monotonic decreasing ($\gamma < 1$) or increasing ($\gamma > 1$). The Weibull distribution has a variety of forms, depending on γ , and has simple formulas for survival and hazard functions, so it is widely used in the parametric analysis of failure time data. In general, gamma and log-normal distributions are less convenient to compute, but are still frequently used. The Weibull hazard function is a monotonic function of time; however, the log-logistic hazard function $h(t) = \exp(\theta)\kappa t^{\kappa-1}/(1 + \exp(\theta)t^\kappa)$ is monotonic decreasing if $0 < \kappa \leq 1$, and has a single mode if $\kappa > 1$. Furthermore, the log-logistic distribution has a simple algebraic expression for the survival function $S(t) = (1 + \exp(\theta)t^\kappa)^{-1}$, and it is therefore an alternative to the Weibull distribution in situations where the hazard function changes direction. It is also more convenient than the log-normal distribution for handling censored data.

Let $t_{(1)} < \dots < t_{(m)}$ be m ordered failure times with $t_{(m+1)} = \infty$, and let r_j and d_j be the number of individuals at risk of failure and the number of observed failures at time $t_{(j)}$, respectively. The Kaplan–Meier^[1] (product–limit) estimator of the survival function is most commonly used and is expressed as

$$\hat{S}_{\text{KM}}(t) = \prod_{j=1}^k \left(1 - \frac{d_j}{r_j} \right) \quad (1)$$

for $t_{(k)} \leq t < t_{(k+1)}$, $k = 1, \dots, m$, with $\hat{S}_{\text{KM}}(t) = 1$ for $t < t_{(1)}$. Note that $\hat{S}_{\text{KM}}(t)$ is, strictly speaking, undefined for t greater than the largest observation that is a censored time; $\hat{S}_{\text{KM}}(t) = 0$ for t greater than the largest observation that is the failure time $t_{(m)}$, because $r_m = d_m$. In the absence of censoring, the Kaplan–Meier estimator is an empirical survival function, and therefore is a generalization of the empirical survival function to accommodate censored observations.

The Nelson–Aalen estimator,^[2,3] also called Altshuler's estimator,^[4] is an alternative estimator of the survival function, given by

$$\hat{S}_{\text{NA}}(t) = \prod_{j=1}^k \exp \left(-\frac{d_j}{r_j} \right) \quad (2)$$

which is obtained from an estimator of the cumulative hazard function $H(t) = -\log S(t)$, denoted by $\hat{H}_{\text{NA}}(t) = \sum_{j=1}^k d_j/r_j$ for $t_{(k)} \leq t < t_{(k+1)}$. These two estimates are asymptotically equivalent, but the Kaplan–Meier estimate is always less than the Nelson–Aalen estimate, because $\exp(-d_j/r_j) \geq 1 - d_j/r_j$. Colosimo et al.^[5] studied small-sample properties of these estimators by performing Monte Carlo simulations. Their results showed the Nelson–Aalen estimator to be slightly superior in survival fraction estimation. However, for percentile estimation, the Kaplan–Meier estimator showed better performance for decreasing failure rates while the Nelson–Aalen estimator outperformed the Kaplan–Meier estimator for increasing failure rates.

The standard error of the Kaplan–Meier estimator can be obtained by Greenwood's formula.^[6] Greenwood's formula can underestimate the variance of the estimated survival function when it is close to zero or one. Instead, one can use a more conservative standard error proposed by Peto et al.,^[7] which tends to be larger than it should be. However, the Greenwood estimate is recommended for general use.

PROPORTIONAL HAZARDS MODELS

Assume that $\mathbf{x} = (x_1, \dots, x_p)$ is a vector of covariates for an individual and that $h(t; \mathbf{x})$ is the hazard rate at time t for the individual with covariates $\mathbf{x}$. Cox^[8] assumed that the

covariates act multiplicatively on the hazard function and proposed the proportional hazards model (also called the Cox model) as follows:

$$h(t; \mathbf{x}) = h(t) \exp(\mathbf{x}\boldsymbol{\beta}) \quad (3)$$

where $h(t)$ is an arbitrary unspecified baseline hazard function at time t for an individual with covariates equal to zero, and $\boldsymbol{\beta} = (\beta_1, \dots, \beta_p)^T$ is a vector of regression parameters for T denoting transposition. Or, in terms of survival function, we can express survival function of the individual with covariates $\mathbf{x}$ as

$$S(t; \mathbf{x}) = (S(t))^{\exp(\mathbf{x}\boldsymbol{\beta})} \quad (4)$$

where $S(t) = \exp(-\int_0^t h(u) du)$ is the survival function of an individual with covariates equal to 0. That is, in this model the survival function $S(t; \mathbf{x})$ of the individual with covariates $\mathbf{x}$ is the baseline survival function $S(t)$ to a power. The class of models is sometimes called the *Lehmann class*.^[9] Because no particular functional form of the baseline hazard function is assumed, the model is referred to as a *semiparametric regression model*. The proportional hazards regression model (4) can be reformulated as a linear transformation model

$$g(T) = -\mathbf{x}\boldsymbol{\beta} + \varepsilon \quad (5)$$

where $g(T) = \log(-\log(S(T)))$ is a strictly increasing function and $\varepsilon = \log(-\log(S(T; \mathbf{x})))$ has an extreme value (minimum) distribution. If the baseline hazard function is $h(t) = \lambda \gamma t^{\gamma-1}$, the proportional hazards regression model is a Weibull regression model, and the linear transformation model (5) can be written as $\log T = \boldsymbol{\beta}_0^* + \mathbf{x}\boldsymbol{\beta}^* + \sigma\varepsilon$, where $\sigma = \gamma^{-1}$, $\boldsymbol{\beta}_0^* = -\sigma \log \lambda$, and $\boldsymbol{\beta}^* = -\sigma\boldsymbol{\beta}$. Note that if $\gamma = 1$, the model reduces to an exponential regression model.

Estimation

Assume that the observed data consist of the triplets $(t_i, \delta_i, \mathbf{x}_i)$, $i = 1, 2, \dots, n$, where t_i is the observation time of individual i (either the failure time or the censoring time); δ_i is the censoring indicator, which is 1 if t_i is the failure time and 0 otherwise; and $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{ip})$ is the covariate vector of individual i . When the baseline hazard function is specified, the unknown parameters of interest can be estimated by using the method of maximum likelihood.

When the baseline hazard function is unspecified, one can first estimate the regression parameter vector $\boldsymbol{\beta}$ and then construct an estimate of the baseline survival function (or cumulative hazard function) based on the estimate of $\boldsymbol{\beta}$. Assume that failures occur at distinct times, $t_{(1)} < t_{(2)} < \dots < t_{(m)}$. Let $\mathbf{x}_{(i)}$ be the covariate values of the individual that fails at time $t_{(i)}$. Cox^[8,10] proposed the following *partial likelihood* for estimating $\boldsymbol{\beta}$:

$$L(\beta) = \prod_{j=1}^m \frac{\exp(\mathbf{x}_{(j)}\beta)}{\sum_{t \in R(t_{(j)})} \exp(\mathbf{x}_t\beta)} \quad (6)$$

where $R(t_{(j)})$, called the *risk set* at time $t_{(j)}$, is the set of all r_j individuals at risk just prior to $t_{(j)}$. Kalbfleisch and Prentice^[11] showed that in the absence of censoring and time-dependent covariates, the partial likelihood (6) is the marginal likelihood of the ranks.

To accommodate tied observations, Kalbfleisch and Prentice^[12] derived an exact expression for the partial likelihood that has a very complex form. The computation of this exact partial likelihood is very time consuming if there are a large number of ties at any failure time. To overcome the computational burden, a number of approximation methods have been proposed, e.g., Refs. [8,13,14]. For a rigorous proof of the asymptotic properties of the maximum partial likelihood estimator, see, e.g., Refs. [15,16].

Kalbfleisch and Prentice^[11] used an approach based on the method of nonparametric maximum likelihood to derive an estimate of the baseline hazard function at time t and gave the maximum likelihood estimate $\hat{\alpha}_j$ of $\alpha_j = S(t_{(j)})/S(t_{(j-1)})$ as a solution to the following equation:

$$\sum_{t \in \mathcal{D}(t_{(j)})} \frac{\exp(\mathbf{x}_t \hat{\beta})}{1 - \hat{\alpha}_j^{\exp(\mathbf{x}_t \hat{\beta})}} = \sum_{t \in R(t_{(j)})} \exp(\mathbf{x}_t \hat{\beta}) \quad (7)$$

where $\mathcal{D}(t_{(j)})$ is the set of all d_j individuals failing at time $t_{(j)}$. If only a single failure occurs at $t_{(j)}$ (i.e., $d_j = 1$), the solution $\hat{\alpha}_j$ to Eq. 7 can be solved, and, hence, the Kalbfleisch–Prentice estimate of the baseline survival function is

$$\hat{S}_{\text{KP}}(t) = \prod_{j: t_{(j)} \leq t} \left(\frac{1 - \exp(\mathbf{x}_{(j)} \hat{\beta})}{\sum_{t \in R(t_{(j)})} \exp(\mathbf{x}_t \hat{\beta})} \right)^{\exp(-\mathbf{x}_{(j)} \hat{\beta})} \quad (8)$$

If $d_j > 1$, one can have $\hat{S}_{\text{KP}}(t)$ by numerically solving Eq. 7. As a result, the estimated survival function for an individual with covariates $\mathbf{x}$ is $\hat{S}_{\text{KP}}(t, \mathbf{x}) = \hat{S}_{\text{KP}}(t)^{\exp(\mathbf{x} \hat{\beta})}$. Alternatively, to avoid the laborious computation when solving Eq. 7, one can substitute $\hat{\alpha}_j^{\exp(\mathbf{x}_t \hat{\beta})} \approx 1 + \exp(\mathbf{x}_t \hat{\beta}) \log \tilde{\alpha}_j$ into Eq. 7 to obtain $\tilde{\alpha}_j$. With $\tilde{\alpha}_j$'s, one can obtain the estimate of the baseline survival function referred to as the Nelson–Aalen estimate or the Breslow estimate. Note that when there are no covariates, one can see from Eq. 7 that $\hat{S}_{\text{KP}}(t)$ is the Kaplan–Meier estimate as shown in Eq. 1.

ACCELERATED FAILURE-TIME MODELS

In the proportional hazards regression model, the effect of covariates is intuitively assumed to act multiplicatively

on the hazard function, but the model does not propose a direct relationship between failure time and covariates. In contrast, the accelerated failure time (accelerated life) model^[12,17] has an intuitive physical interpretation in which the effect of covariates $\mathbf{x}$ is assumed to act multiplicatively on the failure time T or additively on the log failure time, log T , expressed as:

$$\log T = \mathbf{x}\beta + \epsilon \quad (9)$$

with error density $f(e)$. The accelerated failure time model with unspecified error distribution is called a *semiparametric accelerated failure model* and can be considered a semiparametric alternative to the proportional hazards regression model. Let $h(t^*)$ be the hazard function of $T^* = \exp(\epsilon)$. The hazard function of T can be written in terms of this baseline hazard function $h(\cdot)$ as

$$h(t; \mathbf{x}) = h(t \exp(-\mathbf{x}\beta)) \exp(-\mathbf{x}\beta) \quad (10)$$

where $\exp(\mathbf{x}\beta)$ is referred to as the *accelerated factor*. The survival function of T is $S(t; \mathbf{x}) = S(t \exp(-\mathbf{x}\beta))$. In this model, the role of covariates is to accelerate or decelerate the time to failure. If $h(t) = \lambda \gamma t^{\gamma-1}$, $h(t; \mathbf{x}) = \lambda \exp(-\gamma \mathbf{x}\beta) \gamma t^{\gamma-1}$, and the accelerated failure time model (10) is a Weibull model with scale parameter $\lambda \exp(-\gamma \mathbf{x}\beta)$ and shape parameter γ . The Weibull distribution possesses the accelerated failure time property and is the only probability distribution that has both the proportional hazard property and the accelerated failure time property. Note that if $\gamma = 1$, the accelerated failure time model (10) reduces to an exponential model with scale parameter $\lambda \exp(-\mathbf{x}\beta)$.

If the baseline hazard function is $h(t) = \exp(\theta) \kappa t^{\kappa-1} = (1 + \exp(\theta) t^\kappa)$ for $\kappa > 0$, the hazard function of the individual with covariates $\mathbf{x}$ is $h(t; \mathbf{x}) = \exp(\theta - \kappa \mathbf{x}\beta) \kappa t^{\kappa-1} / (1 + \exp(\theta - \kappa \mathbf{x}\beta) t^\kappa)$, and the accelerated failure time model (10) is a log-logistic model with parameters $\theta - \kappa \mathbf{x}\beta$ and κ . Thus, the log-logistic distribution has the accelerated failure time property. Other distributions that have the accelerated failure time property include the log-normal, gamma, and inverse Gaussian distributions.

Estimation

A number of semiparametric estimators have been proposed for use in estimating the parameters of interest and handling the presence of censored observations when the error density is completely unspecified. For example, Miller^[18] provided the Kaplan–Meier least-squares estimator obtained by minimizing the weighted sum of squares of the residuals, with weights derived from the Kaplan–Meier estimator of the error distribution based on the residuals. Buckley and James^[19] proposed a modification of the least-squares estimator in which censored observations are replaced with an estimate of their expectation, but they gave no mathematical justification and did not provide

a reliable computational method for implementation. Koul et al.^[20] proposed an inverse censoring probability weighted modification of the least-squares estimator. Lai and Ying^[21] rigorously studied the asymptotic properties of the Buckley–James estimator.^[19] Louis^[22] proposed the log-rank test-based estimator in the two-sample problem and studied the asymptotic properties of the estimator, while Wei and Gail^[23] studied corresponding results for a broader class of censored data rank tests. Jones^[24] proposed a general class of nonparametric test statistics, including both linear and nonlinear rank tests for the model, which are inverted into equations for estimating the regression parameters β .

Prentice^[25] proposed rank estimators based on the *weighted log-rank* statistics. The asymptotic properties of the rank estimators were studied by, e.g., Tsiatis^[26] and Ying.^[27] The weighted log-rank estimating functions for β are expressed as:

$$U_{\phi}(\beta) = \sum_{i=1}^n \delta_i \phi(\beta; e_i(\beta)) (\mathbf{x}_i - \bar{\mathbf{x}}(\beta; e_i(\beta))) \quad (11)$$

where ϕ is a possibly data-dependent weight function and $e_i(\beta) = \log t_i - \mathbf{x}_i \beta$, $\bar{\mathbf{x}}(\beta, u) = S^{(1)}(\beta; u) / S^{(0)}(\beta; u)$ for $S^{(0)}(\beta; u) = n^{-1} \sum_{i=1}^n I(e_i(\beta) \geq u)$ and $S^{(1)}(\beta; u) = n^{-1} \sum_{i=1}^n \mathbf{x}_i I(e_i(\beta) \geq u)$, with $I(\cdot)$ being the indicator function. If $\phi(\beta; e_i(\beta)) = 1$, then $U_{\phi}(\beta)$ is the log-rank^[28] statistic. If $\phi(\beta; u) = \prod_{j: e_j(\beta) \leq u} n S^{(0)}(\beta; e_j(\beta)) / (n S^{(0)}(\beta; e_j(\beta)) + 1)$, then $U_{\phi}(\beta)$ is the generalized Wilcoxon statistic. When $\phi(\beta; u) = S^{(0)}(\beta; u)$, $U_{\phi}(\beta)$ is the Gehan^[29] statistic. $U_{\phi}(\beta)$ is a p -dimensional step function of β that need not be monotonic, so in general, no exact solutions to the system of equations $U_{\phi}(\beta) = 0$ can be obtained. Wei et al.^[30] suggested choosing $\hat{\beta}$ that minimizes $\|U_{\phi}(\beta)\|$, where $\|\cdot\|$ is the Euclidean norm. Fygenon and Ritov^[31] studied the monotonicity properties of the weighted log-rank estimating function $U_{\phi}(\beta)$ in Eq. 11 and characterized the class of weight functions for which the weighted log-rank estimating function 11 is a monotonic function of each component of β . They noted that the Gehan estimating function is in this class, but the log-rank and generalized Wilcoxon estimations are not.

The theoretical results of the semiparametric accelerated failure time models have been well developed, but the semiparametric methods have not been widely used in practice, because no efficient and reliable computational methods are available to address the problem of minimizing $\|U_{\phi}(\beta)\|$, which is discontinuous and may have multiple local minima. Because the problem of minimizing $\|U_{\phi}(\beta)\|$ cannot be solved by the conventional optimization algorithms, Lin and Geyer^[32] applied the simulated annealing method^[33] to calculate $\hat{\beta}_{\phi}$ when the dimension of β is too large to permit a direct grid search; however, as Jin et al.^[34] pointed out, their algorithm is not guaranteed to yield the true minimum. To solve the numerical problem, Jin et al.^[34] provided a simple and reliable method in which they introduced a

class of monotonic estimating functions to approximate the weighted log-rank estimating function $U_{\phi}(\beta)$ in Eq. 11 by

$$\begin{aligned} \tilde{U}_{\phi}(\beta; \hat{\beta}) &= \sum_{i=1}^n \delta_i \psi(\hat{\beta}, e_i(\beta) + \mathbf{x}_i(\beta - \hat{\beta})) S^{(0)}(\beta; e_i(\beta)) \\ &\quad \times (\mathbf{x}_i - \bar{\mathbf{x}}(\beta; e_i(\beta))) \\ &= n^{-1} \sum_{i=1}^n \sum_{j=1}^n \psi(\hat{\beta}; e_i(\hat{\beta})) \delta_i (\mathbf{x}_i - \mathbf{x}_j) I(e_i(\beta) \leq e_j(\beta)) \end{aligned}$$

where $\psi(b; u) = \phi(b; u) / S^{(0)}(b; u)$ and $\hat{\beta}$ is a preliminary consistent estimator of β , such as the Gehan estimator. $\tilde{U}_{\phi}(\beta; \hat{\beta})$ is monotonic in each component of β and is the gradient of

$$L_{\phi}(\beta; \hat{\beta}) = n^{-1} \sum_{i=1}^n \sum_{j=1}^n \psi(\hat{\beta}; e_i(\hat{\beta})) \delta_i |e_i(\beta) - e_j(\beta)| I(e_i(\beta) - e_j(\beta) < 0) \quad (12)$$

Thus, $\hat{\beta}_{\phi}$ can be found by the iterative algorithm: $\hat{\beta}_{(0)} = \hat{\beta}$, $\hat{\beta}_{(k)} = \arg \min_{\beta} L_{\phi}(\beta; \hat{\beta}_{(k-1)})$ for $k \geq 1$, in which the minimization of $L_{\phi}(\beta; \hat{\beta}_{(k-1)})$ can be accomplished by linear programming. The resulting estimator is consistent, although the original estimating equation may contain inconsistent roots, and is asymptotically normal.^[34]

PROPORTIONAL ODDS MODELS

Bennett^[35] generalized the proportional odds model to the survival analysis context and fit the model to the data set from the Veterans Administration lung cancer trial.^[36] The model assumes that the covariates $\mathbf{x}$ have a multiplicative effect on the odds against survival beyond time t , expressed as

$$\frac{1 - S(t; \mathbf{x})}{S(t; \mathbf{x})} = \frac{1 - S(t)}{S(t)} \exp(\mathbf{x}\beta) \quad (13)$$

where $(1 - S(t; \mathbf{x})) / S(t; \mathbf{x})$ is the odds of the occurrence of an event of interest by time t for the individual with covariates $\mathbf{x}$, and $R(t) = (1 - S(t)) / S(t)$ is an unknown baseline odds for the occurrence of the event of interest by time t for an individual with covariates equal to 0. Model (13) is called a *semiparametric proportional odds model*, because the form of the baseline odds $R(t)$ is unspecified.

From model (13), the hazard function of the individual with covariates $\mathbf{x}$ can be expressed as

$$h(t; \mathbf{x}) = \frac{1}{R(t) + \exp(-\mathbf{x}\beta)} \frac{dR(t)}{dt} \quad (14)$$

In terms of hazard ratio, the proportional odds regression model (13) can be written as $h(t; \mathbf{x}) / h(t) = (1 + (\exp(-\mathbf{x}\beta) - 1))$

$S(t)^{-1}$. It is structurally similar to the Cox proportional hazards model and may be used in similar situations. However, whereas the hazard ratio is constant in the Cox model, it converges monotonically from $\exp(\mathbf{x}\boldsymbol{\beta})$ to unity with time in the proportional odds model. This feature can be more useful than the constant hazard ratio when initial effects, such as differences in the stage of disease or in treatment, disappear with time. It may also be appropriate to demonstrate an effective cure, when the mortality rate of the disease group approaches that of a control population.^[35] One can reformulate the proportional odds regression model (13) as a linear transformation model

$$g(T) = -\mathbf{x}\boldsymbol{\beta} + \epsilon \quad (15)$$

where $g(T) = \log R(t)$ is a strictly increasing function and $\epsilon = \log((1-S(T;\mathbf{x}))/S(T;\mathbf{x}))$ has the standard logistic distribution. The proportional odds model can be considered to be a proportional hazards model with unobservable heterogeneity.^[37] If the baseline survival function is the survival function of a log-logistic distribution with unknown parameters θ and κ , the linear transformation model (15) is a log-logistic regression model expressed as $\log T = \beta_0^* + \mathbf{x}\boldsymbol{\beta}^* + \epsilon^*$, where $\boldsymbol{\beta}_0^* = \theta/\kappa$, $\boldsymbol{\beta}^* = -\boldsymbol{\beta}/\kappa$, and $\epsilon^* = \epsilon/\kappa$. The log-logistic distribution has the proportional odds property and is the only one distribution that possesses both the accelerated failure time and proportional odds properties.

Estimation

Methods of estimating $\boldsymbol{\beta}$ in model (13) have been proposed by a number of authors, including, e.g., Bennett,^[35] who used a *profile likelihood* approach; Pettitt,^[38] who applied a rank-based method; Cheng et al.,^[39] who used an estimating equation approach; and Rossini and Tsiatis,^[40] Huang and Rossini,^[41] and Shen,^[42] who used a *sieve maximum likelihood* approach for current status data, interval-censored data, and right-censored and interval-censored data, respectively.

In general, the approach of Cheng et al.^[39] requires nonparametric estimation of the conditional censoring distribution, given the covariates. Murphy et al.^[37] showed that the estimator based on the profile likelihood approach of Bennett^[35] is asymptotically efficient. The profile likelihood approach requires simultaneous estimation of the regression parameters and the unknown baseline odds function $R(t)$. The computation of the profile likelihood is complex.

Yang and Prentice^[45] derived three classes of estimators to avoid the complex calculation of the profile likelihood while retaining good efficiency properties and the strong assumptions about the censoring patterns or distributions of covariate, and to consider estimation problem in the general proportional odds regression model with censored data, rather than a two-sample case considered by

Dabrowska and Doksum^[43] and Wu.^[44] These estimators, including *pseudomaximum likelihood estimators*, *martingale residual-based estimators*, and *minimum distance estimators*, were derived via some *weighted empirical odds functions*. These estimators are computed easily and are asymptotically normally distributed, and the asymptotic covariance was estimated reliably in closed form. To describe the three classes of estimators, define $x_{i0} = 1$, $i = 1, \dots, n$. For $0 \leq t < \infty$, $j = 0, 1, \dots, p$, and fixed $\mathbf{b} = (b_1, \dots, b_p)^T$, we define the following *weighted empirical processes*: $\hat{W}_{nj}(t) = \sum_{i=1}^n \delta_i x_{ij} I(t_i \leq t)$, $\hat{W}_{nj}(t; \mathbf{b}) = \sum_{i=1}^n \delta_i x_{ij} \exp(-\mathbf{x}_i \mathbf{b}) I(t_i \leq t)$, and $\hat{K}_{nj}(t) = \sum_{i=1}^n x_{ij} I(t_i \geq t)$. For $t \leq t_{nj} = \sup\{s: \hat{K}_{nj}(s) > 0\}$, $j = 0, 1, \dots, p$, we define $\hat{H}_{nj}(t) = \int_0^t \frac{1}{\hat{K}_{nj}(u)} d\hat{W}_{nj}(u)$, $\hat{S}_{nj}(t) = \prod_{u \leq t} (1 - \Delta \hat{H}_{nj}(u))$, and $\hat{H}_{nj}(t; \mathbf{b}) = \int_0^t \frac{1}{\hat{K}_{nj}(u)} \hat{W}_{nj}(du; \mathbf{b})$, where $\Delta g(u) = g(u) - g_{-}(u)$ for any function g and the subscript “ $-$ ” denotes the left-continuous version of a function. Note that $\hat{H}_{n0}(t)$ and $\hat{S}_{n0}(t)$ are the usual Nelson–Aalen and Kaplan–Meier estimators. By multiplying both sides of Eq. 14 by the denominator of its right-hand side, we obtain the following first-order linear integral equation:

$$R(t) = \int_0^t \sum_{i=1}^n a_i(u) (R(u) + \exp(-\mathbf{x}_i \mathbf{b})) dH(u; \mathbf{x}_i) \quad (16)$$

where the $a_i(u)$ s are any negative functions such that $\sum_i a_i(u) = 1$, and $H(u; \mathbf{x}_i)$ is the cumulative hazard function of individual i with covariates $\mathbf{x}_i$. As in Eq. 16 with $a_i(u) = x_{ij} S(u; \mathbf{x}_i) (1 - G_i(u)) / (\sum_{k=1}^n x_{kj} S(u; \mathbf{x}_k) (1 - G_k(u)))$, with $S(u; \mathbf{x}_i)$ and $G_i(u)$ being the survival and censoring functions of individual i with covariates $\mathbf{x}_i$, for $t \leq t_{nj}$ and $j = 0, 1, \dots, p$, we can define the following weighted empirical odds functions

$$\hat{R}_{nj}(t; \mathbf{b}) = \frac{1}{\hat{S}_{nj}(t)} \int_{u \leq t} \hat{S}_{nj-}(u) \hat{H}_{nj}(ds; \mathbf{b}) \quad (17)$$

The first class of estimators is derived on the basis of the score function of $\boldsymbol{\beta}$ obtained by differentiating the likelihood function with respect to $\boldsymbol{\beta}$ by assuming that $R(t)$ is known. By replacing $R(t)$ by $\hat{R}_{n0}(t; \mathbf{b})$ in the score function of $\boldsymbol{\beta}$, Yang and Prentice^[45] defined a pseudomaximum likelihood estimator of $\boldsymbol{\beta}$ to be the solution to the system of estimating equations

$$\sum_{i=1}^n \mathbf{x}_i \frac{\delta_i \exp(-\mathbf{x}_i \mathbf{b}) - \hat{R}_{n0}(t_i; \mathbf{b})}{\exp(-\mathbf{x}_i \mathbf{b}) + \hat{R}_{n0}(t_i; \mathbf{b})} = 0 \quad (18)$$

which are asymptotically unbiased in the sense that replacing $\hat{R}_{n0}(u; \mathbf{b})$ by $R(u)$ results in the system of unbiased estimating equations.

The second class of estimators is derived from the martingale residuals $M_i(t) = \delta_i I(t_i \leq t) - \int_0^t I(t_i \geq s) \frac{dR(s)}{R(s) + \exp(-\mathbf{x}_i \boldsymbol{\beta})}$, and a martingale residual-based estimator of $\boldsymbol{\beta}$ is defined as the solution to the system of estimating equations

$$\sum_{i=1}^n \int_0^\infty J_i(t; \mathbf{b}) \hat{M}_i(dt; \mathbf{b}) = 0 \quad (19)$$

where the J_i 's are p -dimensional data-dependent functions and $M_i(t; \mathbf{b})$ is defined by replacing $R(t)$ with $R_{n0}(t; \mathbf{b})$ in $M_i(t)$. Note that for the Cox model, $J_i(t; \mathbf{b}) = \mathbf{x}_i$ gives the maximum partial likelihood estimator, and $J_i(t; \mathbf{b}) = \mathbf{x}_i \hat{S}_{n0}(t; \mathbf{b})$ gives the Peto–Prentice^[25,46] version of generalized Wilcoxon test statistic.

The third class of estimators is obtained by minimizing some discrepancy measures between the $\hat{R}_{nj}(t; \mathbf{b})$ functions, $j = 1, \dots, p$, and $\hat{R}_{n0}(t; \mathbf{b})$, or between the $\hat{F}_{nj}(t; \mathbf{b})$ functions and $\hat{F}_{n0}(t; \mathbf{b})$, where $\hat{F}_{nk}(t; \mathbf{b}) = \hat{R}_{nk}(t; \mathbf{b}) / (1 + \hat{R}_{nk}(t; \mathbf{b}))$ are weighted empirical distribution functions, $k = 0, 1, \dots, p$. In particular, Yang and Prentice^[45] defined a minimum L_2 distance estimator of $\boldsymbol{\beta}$ as the minimizer of the following distance

$$\int_0^\infty \sum_{j=1}^p (\hat{F}_{nj}(t; \mathbf{b}) - \hat{F}_{n0}(t; \mathbf{b}))^2 \Phi_n(dt; \mathbf{b}) \quad (20)$$

with some integrating measure Φ_n possibly dependent on the data. Their numerical studies showed that the minimum L_2 distance estimators with properly chosen integrating measures had the overall best performance among the three classes of estimators and were comparable to the estimator of Cheng et al.^[39] and the maximum profile likelihood estimator.

OTHER ISSUES

Cox^[8] included time-dependent covariates in a proportional hazards model and gave an appropriate partial likelihood for estimating the regression parameters. For a detailed account of the construction of the partial likelihood, see, e.g., Kalbfleisch and Prentice.^[12] Time-dependent covariates included in the Cox model can be used to examine the assumption of proportional hazards in the Cox model. Ataman and De Stavola^[47] discussed a number of practical problems encountered in survival analysis with time-dependent covariates.

The accelerated failure time model with time-dependent covariates was introduced by Cox and Oakes.^[17] Robins and Tsiatis^[48] derived a class of semiparametric rank estimators for the parameters for this model; Lin and Ying^[49] studied the asymptotic properties of the estimators obtained from the log-rank estimating

function and applied their methodology to the Stanford heart transplant data.

Yang and Prentice^[45] reported that the semiparametric proportional odds model (13) can be extended to incorporate time-dependent covariates, and they briefly stated that their corresponding self-consistency integral equations for the regression parameters could still be solved, and that the weighted odds function approach was still available.

In survival analysis, it is common to see that estimated survival curves level off at a nonzero value after a certain time, even when many individuals are followed beyond that time. The data typically have heavy censoring at the end of the follow-up period. The population can be viewed as consisting of two groups of individuals: those who are not susceptible to the event of interest, and those who will be susceptible if they are followed long enough. Therefore standard methods of survival analysis are inappropriate for this type of censored data, and they should be adapted. A number of parametric and semiparametric cure (or mixture) models have been proposed, see, e.g., Refs.^[50–58]. The identifiability of cure models was discussed by Li et al.^[59]

CONCLUSION

The numerical problem of estimating the parameters for the semiparametric accelerated failure time model is challenging, but over the past decade, the model has received a lot of attention, and much progress on solving the numerical problem has been made, such that the model is considered a practical alternative to the Cox model. The accelerated failure time model proposes a direct relationship between failure time and covariates, and this natural type of regression relationship led Sir David Cox to remark that “accelerated life time models are in many ways more appealing” than the proportional hazards model “because of their quite direct physical interpretation.”^[60]

The semiparametric proportional odds model with the property of providing a converging hazard is used as an alternative to the Cox model, but further investigation, especially of the model with time-dependent covariates, is needed to make the model a more useful alternative to the Cox model in survival analysis.

Survival analysis topics not discussed herein were surveyed by Oakes,^[61] with special emphasis on methodology reported in Biometrika.

Abstract

The development of biosimilar products provides a more affordable alternative to general patient population, compared to the brand-name products. However, the availability of more and more biosimilar products in the marketplace also raises a critical issue, that is, whether these biosimilars can be used interchangeably with the brand-name products is unknown. To this end, a crossover design is necessarily employed. In this entry, we focus on the advantages of complete *N*-of-1 designs compared to the commonly used crossover designs. Specifically, the relative efficiency and power analysis are performed for the complete *N*-of-1 designs with two, three, and four dosing periods. As a result, complete *N*-of-1 designs are more efficient and require less sample size in clinical trials. Therefore, complete *N*-of-1 designs are superior than partial designs in general and can potentially work for the evaluation in rare diseases.

Keywords: Biosimilars; Clinical trials; Complete *N*-of-1 designs; Drug interchangeability; Power analysis; Rare diseases; Relative efficiency.

INTRODUCTION

Biological products as therapeutic agents are made from a variety of living cells or living organisms.^[1] The application of biologics ranges from treating disease and medical conditions to preventing and diagnosing diseases. In practice, due to the expensive cost to access to the original biologics, the alternative products (follow-on biologics or biosimilars) are often produced by biopharmaceutical and biotechnology companies. The popularity of biosimilars brings not only advantages but also several critical issues. For benefits, considering that patents of the early biological products will expire in the next few years, biosimilars with the reduction of the cost are more affordable to general patient population. However, biosimilar products need to be demonstrated to be equivalent to the originator product in terms of safety and efficacy before they can be released in the marketplace. According to the FDA, a biological product may be demonstrated to be biosimilar if data show that, among other things, the product is “highly similar” to an already-approved biological product.^[2] To this end, the relevant properties of the biosimilar products are compared with those of the original drugs. If a proposed biosimilar product has been demonstrated to be highly similar to the originator product, the proposed biosimilar product will be approved by the regulatory authority. An approved biosimilar product can be used as a substitute for the originator product for

treating patients with the diseases under study. In practice, as more and more biosimilar products become available in the marketplace, interesting questions have been raised.^[3] The questions are whether approved biosimilar products can be used interchangeably with the originator product and whether the approved biosimilar products can be used interchangeably with other approved biosimilar products.

As indicated in the Biologics Price Competition and Innovation (BPCI) Act passed by the US Congress in 2009, a proposed biosimilar product is considered interchangeable (1) if it is highly similar to the originator (reference) product and can be expected to produce the same clinical result as the reference product in any given patient, and (2) if the biological product is administered more than once to an individual, the risk in terms of safety or diminished efficacy of alternating or switching between the use of the biological product and the reference product is not greater than the risk of using the reference product without such alternation or switch. Thus, the assessment of drug interchangeability of biosimilar products includes the evaluation of (1) the risk in terms of safety and diminished efficacy of alternating or switching between the use of the biological product and the reference product, (2) the risk of using the reference product without such alternation or switch, and (3) the relative risk between switch/alternation and without switch/alternation. For this purpose, a crossover design is necessarily employed. In recent years, three types of hybrid parallel-crossover designs are commonly

used to address the drug interchangeability: the parallel plus 2×2 crossover design, the parallel plus 2×3 crossover design, and the parallel plus 2×4 crossover design. These designs evaluate the drug interchangeability of biosimilars to some extent, but with insufficient efficiency. On the contrary, the complete *N*-of-1 designs assess the drug interchangeability more efficiently than those common crossover designs, especially for the rare diseases.

Complete *N*-of-1 design with S periods is an $N^S \times S$ crossover design where N is the number of drugs. Under S dosing periods, the complete *N*-of-1 design gives all possible combinations of drugs in each of the S dosing periods, which results in N^S sequences. Compared to the commonly used crossover designs, the complete *N*-of-1 designs provide more information when conducting the clinical trials, which allow us to evaluate drug interchangeability. Due to their sensitivity, the complete *N*-of-1 designs potentially work for rare diseases. Considering the rareness of some specific diseases, the number of subjects that can enroll in the trial will be small. With limited participants under the study, the complete *N*-of-1 trial has more advantages to evaluate drug interchangeability than common designs. Actually, the popular designs mentioned above are motivated from a complete *N*-of-1 design with two, three, and four dosing periods, respectively.

Therefore, this article aims to demonstrate the superiority of complete *N*-of-1 designs compared to the popular designs with the corresponding dosing periods and to discuss the potential application of complete *N*-of-1 designs. In Section “Complete *N*-of-1 Design,” the complete *N*-of-1 designs with two, three, and four dosing periods will be introduced. In Section “Comparison between Complete *N*-of-1 Designs and Common Designs,” the comparison of complete *N*-of-1 designs will be discussed in terms of relative efficiency and sample size calculation (Fig. 1). Finally, brief conclusions will be marked according to the analysis results.

Fig. 1 Relative efficiency between complete *N*-of-1 design and partial design

COMPLETE N-OF-1 DESIGN

Complete *N*-of-1 Design with Two Periods

Complete *N*-of-1 design with two periods is a 4×2 crossover design with four sequences and two periods (see Table 1). It is also called Balaam's design, which is a popular design to evaluate the switching for biosimilars. With all possible arrangements of testing and reference drugs, the part of interchangeability, the switching, can be comprehensively assessed under this crossover design. For example, starting from the testing drug, the switch from T to T can be compared to the switch from T to R to evaluate the drug biosimilarity. When using the reference drug at first, the switch from R to R and R to T can also be compared by using group 2 and group 4. However, it cannot assess the alternation due to the limited number of periods in this study design, since alternation requires two switches for each subject.

Complete *N*-of-1 Design with Three Periods

Complete *N*-of-1 design with three periods is an 8×3 design which contains all the possible arrangements for the switching and alternation among testing drugs and reference drugs under three periods (see Table 2).

One of the popular designs to evaluate drug interchangeability is 2×3 dual crossover design, which is a partial design derived from the *N*-of-1 design (see Table 3). This design can evaluate both the switching and the alternation. To compare switching, the switch from T to R and the switch from R to T can be compared within the same cohort of subjects in group 1. Similarly, the switch from R to T and the switch from T to R can be compared within

16	T	T	T	R

group 2. What is more, the switch between T and R can be compared to a different group of subjects as well. However, this crossover design has the problem with the assessment of alternations within the same group of subjects. For example, the alternations of (T to R to T) and (R to T to R) can only be compared to a different group of patients.

Complete *N*-of-1 Design with Four Periods

The 2×4 replicated crossover design contains two sequences and four periods (see Table 4), which is suitable for evaluating both the switching and the alternation, especially the alternations within the same group of subjects. For instance, the alternations of (T to R to T) and (R to T to R) can be evaluated by comparing the drug effect from Period I to Period III to that from Period II to Period IV within the first group of patients.

The 2×4 replicated crossover design is not a complete *N*-of-1 design either. With four periods, qualified subjects will be randomly assigned to the 16 treatment sequences to evaluate the drug interchangeability (see Table 5).

Under the complete *N*-of-1 crossover design with four dosing periods, all possible switching and alternations can be assessed, and the results can be compared within the same group of patients and between different groups of patients.

COMPARISON BETWEEN COMPLETE *N*-OF-1 DESIGNS AND COMMON DESIGNS

Although the partial designs such as 2×3 dual design and 2×4 replicated design can assess drug interchangeability to some extent, complete *N*-of-1 designs are more suitable because they bring a broader framework for evaluation. For instance, outcomes under all possible switches and alternations can be utilized to demonstrate drug interchangeability for the complete *N*-of-1 design with four periods. Compared to the 2×4 replicated design, the complete *N*-of-1 design contains more information for testing and reference drugs, which provides the opportunity to comprehensively assess the drug biosimilarity and interchangeability.

As for the relative efficiency, the partial designs are less efficient than the complete *N*-of-1 design with a corresponding number of periods. To achieve the expected power for evaluating the biosimilarity/interchangeability under two common hypotheses, the partial design requires a larger sample size than the complete design. Because of the smaller sample size required in the complete *N*-of-1 design, conducting the drug trial under the complete design will save money, time, and be more efficient than the partial design.

The comparison of drug interchangeability between complete *N*-of-1 designs and commonly considered designs with the same periods will be discussed in detail. The evaluation between the two designs is based on the relative efficiency adjusting for the carryover effect. The sample size for testing different hypotheses under the two study designs are also calculated.

Relative Efficiency

As it can be seen, the commonly considered designs and complete *N*-of-1 trial designs discussed in Section “Complete *N*-of-1 Design” can be generally described as a $J \times K$ crossover design. Thus, in this section, the drug effect and the carryover effect will be assessed using the following statistical model under a general K -sequence and J -period crossover design comparing two drugs:

$$Y_{ijk} = \mu + G_k + S_{ik} + P_j + D_{d(j,k)} + C_{d(j-1,k)} + e_{ijk}$$

$$i = 1, 2, \dots, n_k; j = 1, 2, \dots, J; k = 1, 2, \dots, K; d = T \text{ or } R$$

where μ is the overall mean, G_k is the fixed k th sequence effect, S_{ik} is the random effect for the i th subject within the k th sequence with mean 0 and variance σ_s^2 , P_j is the

fixed effect for the j th period, $D_{d(j,k)}$ is the drug effect for the drug at the k th sequence in the j th period, $C_{d(j-1,k)}$ is the carryover effect, and e_{ijk} is the random error with mean 0 and variance σ_e^2 . Under the model, it is assumed that S_{ik} and e_{ijk} are mutually independent.

Complete N-of-1 Design with Four Periods vs. RRRR/RTRT Design

Taking the complete N-of-1 design with four periods as an example, the complete design will be compared with a recently popular 2×4 design, which is the RRRR/RTRT design. This partial design from the complete N-of-1 design is proposed and supported by many physicians for evaluating the switching between R and T and the relative risk of with/without alternation (see Table 6).

To compare the relative efficiency between the complete and partial designs, the statistics for testing biosimilarity/bioequivalence between biosimilar drug and reference drug under two study designs are derived.

Under the statistical model, the expected values of the sequence-by-period means for the RRRR/RTRT design are derived based on the above model, which contains for the first-order carryover effect (see Table 7), and the corresponding analysis of variance table is presented in Table 8.

Denote P as a parameter vector, referring to $(\mu, G_1, G_2, P_1, P_2, P_3, P_4, D_T, D_R, C_T, C_R)$, which contains all unknown parameters in the model. The aim is to construct a method of moments estimator in linear form of the observed cell means $\tilde{Y} = \beta' \bar{Y}$, where $\bar{Y}$ is the vector of observed cell means (Table 6).

$$\bar{Y} = (\bar{Y}_{.11}, \bar{Y}_{.21}, \bar{Y}_{.31}, \bar{Y}_{.41}, \bar{Y}_{.12}, \bar{Y}_{.22}, \bar{Y}_{.32}, \bar{Y}_{.42})', \bar{Y}_{.jk} = \frac{\sum_{i=1}^{n_k} Y_{ijk}}{n_k}$$

Then $E(\tilde{Y}) = E(\beta' \bar{Y}) = L'P$ which is the parameter of interest based on the linear contrast L .

In the (RRRR, RTRT) design, let $\omega = (\omega_{11}, \omega_{21}, \omega_{31}, \omega_{41}, \omega_{12}, \omega_{22}, \omega_{32}, \omega_{42})'$ be the vector of expected values for all the cells, where ω_{jk} is the expected value at the k th sequence and j th period, e.g., $\omega_{11} = \mu + G_1 + P_1 + D_R$.

Table 6 RRRR/RTRT design

2	$\mu + G_2 + P_1 + D_R$	$\mu + G_2 + P_2 + D_T + C_R$	$\mu + G_2 + P_3 + D_R + C_T$	$\mu + G_2 + P_4 + D_T + C_R$

Table 8 Analysis of variance table for RRRR/RTRT design

Source of variation	Degree of freedom
Intersubject	$n_1 + n_2 - 1$
Sequence	1
Residual	$n_1 + n_2 - 2$
Intra-subject	$n_1 + n_2$
Period	3
Formulation	1
Carryover	1
Residual	$n_1 + n_2 - 5$
Total	$2(n_1 + n_2) - 1$

According to Table 6, $\omega = X'P$ with X a design matrix given in the below.

$$X = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 1 \\ 1 & 1 & 1 & 1 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 1 & 1 & 1 & 1 & 0 & 1 \end{pmatrix}, \beta = \begin{pmatrix} \beta_{11} \\ \beta_{21} \\ \beta_{31} \\ \beta_{41} \\ \beta_{12} \\ \beta_{22} \\ \beta_{32} \\ \beta_{42} \end{pmatrix}$$

Setting $E(\beta' \bar{Y}) = L'P$ implies that $\beta' \omega = L'P \Rightarrow \beta' X'P = L'P$. Thus, in order to have $E(\beta' \bar{Y}) = L'P$, we should set $\beta' X' = L' \Rightarrow L = X\beta$. Therefore, the method of moments estimate for $L'P$ is $\beta' \bar{Y}$ with $\beta = (X'X)^{-1} X'L$.

The linear contrast L can be chosen based on the parameter of interest. For testing the difference in drug effect $D = D_T - D_R$, we set $L = (0, 0, 0, 0, 0, 0, 1, -1, 0, 0)'$. For testing the difference in carryover effect $C = C_T - C_R$, we set $L = (0, 0, 0, 0, 0, 0, 0, 0, 1, -1)'$.

Table 9 provides the β 's needed to estimate D_R , D_T , and $D_T - D_R$, respectively, with three sets of contrasts, $L = (0, 0, 0, 0, 0, 0, 0, 1, 0, 0)'$, $L = (0, 0, 0, 0, 0, 0, 0, 0, 1, 0)'$, and $L = (0, 0, 0, 0, 0, 0, 1, -1, 0, 0)'$. Notice that considering the design matrix X is not a squared matrix, generalized inverse (the Moore–Penrose generalized inverse) is needed to obtain a unique solution.

Based on β 's for estimating $D_T - D_R$, we have the following unbiased estimators for drug effect:

Table 9 Coefficients for estimates of drugs in RRRR/RTRT design (adjusting for carryover effect)

Sequence	2β 's to estimate D_R				2β 's to estimate D_T				2β 's to estimate D			
	Period I	Period II	Period III	Period IV	Period I	Period II	Period III	Period IV	Period I	Period II	Period III	Period IV

2	1	-0.5	0	-0.5	-1	0.5	0	0.5	-2	1	0	1

$$\tilde{D} = \frac{1}{2} \left[(2\bar{Y}_{.11} - \bar{Y}_{.21} - \bar{Y}_{.41}) - (2\bar{Y}_{.12} - \bar{Y}_{.22} - \bar{Y}_{.42}) \right]$$

$$E(\tilde{D}) = D_T - D_R, \text{Var}(\tilde{D}) = \frac{3}{2} \sigma_e^2 \left(\frac{1}{n_1} + \frac{1}{n_2} \right).$$

When $n_1 = n_2 = n$, $\text{Var}(\tilde{D}) = \frac{3\sigma_e^2}{n}$.

To test the bioequivalence based on average bioequivalence method,

$$H_0 : |D_T - D_R| > \theta \quad \text{vs.} \quad H_1 : |D_T - D_R| \leq \theta,$$

where θ is the prespecified margin. The null hypothesis will be rejected and the bioequivalence will be demonstrated when the statistic $T_D = \frac{\tilde{D} - \theta}{\hat{\sigma}_e^2 \sqrt{\frac{3}{n}}} > t \left[\frac{\alpha}{2}, n_1 + n_2 - 5 \right]$.

The corresponding confidence interval at α significance level is $\tilde{D} \pm t \left[\frac{\alpha}{2}, n_1 + n_2 - 5 \right] \hat{\sigma}_e^2 \sqrt{\frac{3}{2} \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}$.

Table 11 Analysis of variance table for complete *N*-of-1 design

Source of variation	Degree of freedom
Intersubject	$N - 1$
Sequence	15
Residual	$N - 16$
Intra-subject	N
Period	3
Formulation	1
Carryover	1
Residual	$N - 5$
Total	$2N - 1$

Note: N is the total number of patients enrolled in the study.

To evaluate the biosimilarity in the complete *N*-of-1 design, a similar approach is needed as well to derive the estimated coefficients for estimating the difference in drug effect (Table 10). The analysis of variance table is shown in Table 11.

The coefficients in Table 10 are needed to construct $\tilde{D}$, and we have

$$E(\tilde{D}) = D_T - D_R, \text{Var}(\tilde{D}) = \frac{\sigma_e^2}{11n},$$

where n is the number of subjects enrolled in each sequence (assuming equally allocated).

The null hypothesis will be rejected and the bioequivalence will be demonstrated when the statistic $T_D = \frac{\tilde{D} - \theta}{\hat{\sigma}_e^2 \sqrt{\frac{1}{11n}}} > t \left[\frac{\alpha}{2}, 16n - 5 \right]$. The corresponding confidence interval at α significance level is $\tilde{D} \pm t \left[\frac{\alpha}{2}, 16n - 5 \right] \hat{\sigma}_e^2 \sqrt{\frac{1}{11n}}$.

For a fixed sample size, e.g., $N=48$, the number of patients can be randomly assigned to each sequence in the RRRR/RTRT design is 24, whereas the number of patients can be randomly assigned to each sequence in the complete *N*-of-1 design with four dosing periods is 3. Correspondingly, the variances of drug effects for the (RRRR, RTRT) and complete *N*-of-1 designs when adjusting for the carryover effect are $\sigma_e^2/8$ and $\sigma_e^2/33$, respectively. The relative efficiency between two study designs is 24.24%, indicating that the efficiency of RRRR/RTRT design is 24.24% of the complete *N*-of-1 design. Therefore, the partial design (RRRR/RTRT) is less efficient than the

Table 12 Complete N-of-1 design with two periods

3	0.5	-0.5
4	-0.5	0.5

complete design (N-of-1 design with four periods). Similar analysis can be performed for the comparison between the complete design and the partial design with two periods and three periods.

Complete N-of-1 Design with Two Periods vs. 2 × 2 Crossover Design

As introduced earlier, the complete N-of-1 design with two periods is a Balaam design. The comparison between the Balaam design and the 2 × 2 crossover design (see Table 12) is performed based on the similar procedure.

The estimated coefficients for estimating the difference in drug effect is derived for the complete design (Table 13).

The coefficients in Table 13 are needed to construct $\tilde{D}$, and we have

$$E(\tilde{D}) = D_T - D_R, \text{Var}(\tilde{D}) = \frac{2\sigma_e^2}{n},$$

where n is the number of subjects enrolled in each sequence (assuming equally allocated).

Following the similar procedure, the estimated coefficients for the estimated difference in drug effect is derived for the RR/RT design (Table 14).

$$\text{According to this table, } E(\tilde{D}) = D_T - D_R, \text{Var}(\tilde{D}) = \frac{4\sigma_e^2}{n}$$

when adjusting for the carryover effect.

When the total sample size is 48, 12 patients will be enrolled in each sequence for the Balaam design and 24 patients will be enrolled in each sequence for the 2 × 2 design. Correspondingly, the variances of drug effects for the (RR, RT) design and the complete N-of-1 design when adjusting for the carryover effect are both $\sigma_e^2/6$. The relative efficiency between the two study designs is 100%, indicating that the efficiency of RR/RT design is the same as that of the complete N-of-1 design with two periods.

2	-1	0.5	0.5

Complete N-of-1 Design with Three Periods vs. 2 × 3 Dual Design

Comparing the relative efficiency between the complete N-of-1 design with three periods and the 2 × 3 dual design, we then have the estimated coefficients of difference in drug effect for two designs (Tables 15 and 16).

For the complete design, we have $E(\tilde{D}) = D_T - D_R$, $\text{Var}(\tilde{D}) = \frac{3\sigma_e^2}{10n}$ according to Table 15. For the partial design, we have $E(\tilde{D}) = D_T - D_R$, $\text{Var}(\tilde{D}) = \frac{3\sigma_e^2}{n}$ according to Table 16.

For a sample size of 48, there would be 6 subjects in each sequence for the complete design and 24 subjects in each sequence for the partial design. Then the variances of drug effects for the 2 × 3 dual design and the complete N-of-1 design with three periods when adjusting for the carryover effect are $\sigma_e^2/8$ and $\sigma_e^2/20$, respectively. The relative efficiency between two study designs is 40%, indicating that the efficiency of the RR/RT design is 40% less than that of the complete N-of-1 design with two periods.

Summary

In general, complete *N*-of-1 designs show more efficiency than partial designs with the same number of periods. The relative efficiency has no difference when comparing the complete *N*-of-1 design with two periods to the RR/RT design. However, as the dosing period increases, the relative efficiency is decreasing for the comparison, indicating that the complete designs are superior than the partial designs in terms of relative efficiency. With four dosing periods, the relative efficiency is only 24% comparing the partial design with the complete *N*-of-1 design. Table 17 is a summary table when the sample size is 48 to show the relative efficiencies for comparison with two, three, and four dosing periods.

Power Analysis

The power analysis can be also performed to see the superiority of the complete *N*-of-1 design compared to the partial design. The sample size determination under the fixed power and significance level is derived based on the following hypothesis testing.

$$H_0: |D_T - D_R| > \theta \quad \text{vs} \quad H_1: |D_T - D_R| \leq \theta.$$

According to the $\pm 20\%$ rule, the bioequivalence is concluded if the average bioavailability of the test drug effect is within $\pm 20\%$ of that of the reference drug effect with a certain assurance. Therefore, θ is usually represented by $\nabla \mu_R$ where $\nabla = 20\%$, and the hypothesis testing can be rewritten as follows:

$$H_0: \mu_T - \mu_R \left\langle -\nabla \mu_R \text{ or } \mu_T - \mu_R \right\rangle \nabla \mu_R \quad \text{vs.} \\ H_a: -\nabla \mu_R \leq \mu_T - \mu_R \leq \nabla \mu_R.$$

The power function can be written as

$$P(\theta) = F_v \left(\left[\frac{\nabla - R}{CV \sqrt{b/n}} \right] - t(\alpha, v) \right) \\ - F_v \left(t(\alpha, v) - \left[\frac{\nabla + R}{CV \sqrt{b/n}} \right] \right),$$

Table 17 Summary table for the relative efficiency (sample size = 48)

Dosing periods	Relative efficiency (%)
Two	100
Three	40
Four	24

Table 18 Summary for additive model (with four periods)

	<i>R</i>	
	5%	10%
RRRR/RTRT design	136	300
Complete <i>N</i> -of-1 design	32	48

where $R = \frac{\mu_T - \mu_R}{\mu_R}$ is the relative change; $CV = \frac{S}{\mu_R}$; μ_T, μ_R are the average bioavailability of the test and reference formulations, respectively; S is the squared root of the mean square error from the analysis of variance table for each crossover design; $[-\nabla \mu_R, \nabla \mu_R]$ is the bioequivalence limit; $t(\alpha, v)$ is the upper α th quantile of a *t*-distribution with v degrees of freedom; F_v is the cumulative distribution function of the *t*-distribution; and b is the constant value for the variance of drug effect.

Accordingly, the exact sample size formula when $R = 0$ is $n \geq b \left[t(\alpha, v) + t\left(\frac{\beta}{2}, v\right) \right]^2 [CV/\nabla]^2$; the approximate sample size formula when $R > 0$ is $n \geq b \left[t(\alpha, v) + t(\beta, v) \right]^2 [CV/(\nabla - R)]^2$.

Another way to determine the sample size is based on testing the ratio of the drug effect between the bio-similar product and the reference product. Considering $\delta \in (0.8, 1.25)$ is the bioequivalence range of μ_T/μ_R , the hypothesis changes to

$$H_0: \frac{\mu_T}{\mu_R} \left\langle 0.8 \text{ or } \frac{\mu_T}{\mu_R} \right\rangle 1.25 \quad \text{vs.} \quad H_a: 0.8 \leq \frac{\mu_T}{\mu_R} \leq 1.25.$$

In case of the skewed distribution, the hypotheses are transformed to logarithmic scale:

$$H_0: \log \mu_T - \log \mu_R \left\langle \log(0.8) \text{ or } \log \mu_T - \log \mu_R \right\rangle \log(1.25) \\ \text{vs.} \quad H_a: \log(0.8) \leq \log \mu_T - \log \mu_R \leq \log(1.25)$$

Then, the sample size formulas for different δ 's are given below:

$$n \geq b \left[t(\alpha, v) + t\left(\frac{\beta}{2}, v\right) \right]^2 [CV/\ln 1.25]^2 \quad \text{if } \delta = 1,$$

$$n \geq b \left[t(\alpha, v) + t(\beta, v) \right]^2 [CV/(\ln 1.25 - \ln \delta)]^2 \\ \text{if } 1 < \delta < 1.25,$$

$$n \geq b \left[t(\alpha, v) + t(\beta, v) \right]^2 [CV/(\ln 0.8 - \ln \delta)]^2 \\ \text{if } 0.8 < \delta < 1.$$

To compare the sample sizes between two designs, for instance, we have a summary table (see Table 18) of the number of subjects for the additive models between the RRRR/RTRT design and the complete *N*-of-1 design with four periods under 80% power, $CV = 20\%$, and $\theta = 5\%$ and 10% .

Table 19 summarizes the number of subjects for the multiplicative models between the RRRR/RTRT design and the complete *N*-of-1 design with four periods under 80% power, $CV = 20\%$, and $\delta = 0.90$ and 1.00 .

Table 19 Summary for multiplicative model (with four periods)

	δ	
	0.90	1.00

Complete <i>N</i> -of-1 design	32	16

CONCLUSION REMARKS

Although the drug interchangeability including switching and alternation can be assessed in both the partial design and the complete *N*-of-1 design (especially with four dosing periods), complete *N*-of-1 designs show better performance in terms of relative efficiency and power analysis. With more information, the complete *N*-of-1 design has the advantage of evaluating all possible switches and alternations within one clinical trial. Requiring less number of subjects enrolled in the trial, the complete *N*-of-1 design can be also potentially used in rare disease evaluation. Because of the difficulty in enrolling patients with rare disease, it is important to conduct the clinical trial with moderate sensitivity to detect biosimilarity with a limited

number of patients. Under such situations, complete *N*-of-1 designs are suitable for rare diseases as this kind of crossover designs is more informative and efficient and requires less number of subjects enrolled than partial designs. However, too many sequences in the complete design will cause much fewer subjects to be allocated to each sequence. In case of the withdrawal of subjects, the conduction of complete design may face a missing data issue, which will affect the evaluations more than that in the partial design.

Clinical Trials

Kenneth B. Schechtman

Washington University School of Medicine, St. Louis, Missouri, U.S.A.

Abstract

This entry provides a broad overview of some general principles that govern the design and conduct of clinical trials. Specifically discussed are operational approaches to conducting a randomized and blinded trial and reasons why the absence of randomization, unblinded studies, and loss to follow-up can be major sources of bias in clinical trials.

INTRODUCTION

The randomized clinical trial (RCT) is broadly considered to be the most effective approach to evaluating a new therapeutic modality and to testing an existing therapy in a new setting. In this article, we provide a broad overview of some general principles that govern the design and conduct of clinical trials. Specifically, we discuss operational approaches to conducting a randomized and blinded trial and reasons why the absence of randomization, unblinded studies, and loss to follow-up can be major sources of bias in clinical trials. In addition, we focus on the rationale for the prospective selection of a small number of primary endpoints, for including interim analyses in a trial, and for the use of intention-to-treat when analyzing clinical trial data. Brief discussions of procedural issues that are relevant to the recruitment of clinical trial subjects and to the conduct and structure of multicenter trials are also presented. Because they are discussed elsewhere in this volume, we omit such key issues as sample-size determination, statistical power, compliance to prescribed therapeutic regimens, and data analytic considerations.

DEFINITION

A *clinical trial* is a prospective study in which two or more treatments are compared with one another. All therapeutic arms may be active treatments, or, alternatively, a placebo may be used in one group. The most definitive kind of clinical trial is the randomized trial, which requires that group assignment be the result of some random process beyond the control of both the investigator and the subject. A well-designed clinical trial requires a prospectively written protocol that describes in detail the design of the proposed research. The protocol should include a small number of clearly defined hypotheses, specific aims, and outcome measures. It should also provide a detailed delineation of eligibility and exclusion criteria, a description of

the proposed interventions, discussions of recruitment and randomization processes, a detailed consideration of how the planned study will avoid potential sources of bias, a discussion of the quality control measures that will minimize the potential for errors in the collection and the computerization of data, a justification of the planned sample size, and a presentation of the statistical methods that will be used to evaluate the data.

RANDOMIZATION

The purposes of randomization are as follows. First, to reduce the likelihood that there will be selection bias, the bias that may result when the selected sample is unrepresentative of the target population. Second, to minimize the likelihood that subjective decisions about treatment assignment will yield between-group differences in subject characteristics at baseline. When selection bias yields an unrepresentative sample, it may be difficult to define the population to which study results can be generalized. If one group is either older, sicker, or, otherwise, less likely to benefit from treatment, the apparent success of the alternative therapy may reflect nothing more than the positive prognostic status of the sample that has been assigned to that treatment. While carefully conducted nonrandom treatment assignment may yield balance with respect to known risk factors such as age and disease status, there is no way that subjective processes can address the impact of unknown risk factors. Similarly, while covariate adjustment during the analysis stage may account for the effect of known predictors that differ between groups, you cannot adjust for factors you do not know about.

The theoretical benefits of randomization have been demonstrated in a number of studies that have compared results from randomized trials with those that have used nonrandom treatment allocation.^[1–5] The consistent message is that trials that use nonrandom assignment tend to produce biased overestimates of true therapeutic efficacy.

For example, Sacks et al.^[1] evaluated 50 RCTs and 56 trials that used historical controls (HCTs) and found that 44 of the 56 HCT reports (79%) concluded that the therapy was better than the control regimen, while only 10 of the 50 (20%) reports on RCTs reached this conclusion. Chalmers et al.^[3] used similar methods in comparing the conclusions of RCTs, nonrandomized trials that used concurrent controls (CCTs) and HCTs in evaluating the efficacy of anti-coagulants following acute myocardial infarction. Their conclusion was that efficacy estimates were smallest with RCTs, were second smallest with CCTs, and were largest with HCTs.

It has recently been argued that it is common for investigators to work actively toward a subversion of the randomization process through a variety of approaches to determining in advance the group to which subjects will be assigned.^[6] Careful attention to the mechanics of randomization is essential because inadequately concealed randomization can inflate the odds ratios that estimate treatment effects^[7] by 30–40% and can bias results in the direction of unwarranted significance.^[2] The most commonly used approaches to maximizing the integrity of the process are as follows: (1) the use of numbered opaque and sealed envelopes that contain randomization information and that are opened only after eligibility has been established, and the subject has given informed consent; (2) randomization by telephone or fax communication with a coordinating center (CC) or some other agent that is physically separated from the investigator; (3) randomization using password-protected Web-based systems.

The literature contains many discussions of the scientific approaches to group assignment.^[8–11] Regardless of the mechanics of the process itself, randomization is almost always accomplished using random-number generators to make the assignment. While equal allocation is most common, it is not at all unusual to employ randomization schemes that assign different numbers of patients to different groups. The most basic approach to determining the order of treatment assignment is to use simple randomization, a process whose defining characteristic is that each new treatment assignment is random and is fully independent of all preceding assignments. Two disadvantages of this approach are that the laws of chance mean that simple randomization may yield an imbalance in the number of patients assigned to the various study groups, and, alternatively, there may be temporal bias caused by too many subjects being assigned to one group early in the study and too few at later time points.

To address these problems, *blocked* randomization is often used. When blocking is employed, each consecutive group of k subjects is assigned in some fixed proportion to all study groups. In this way, temporal bias is avoided and the target randomization percentages can be guaranteed. When there is concern that investigators in unblinded studies may use information about block sizes to break randomization codes, it may be best to keep investigators

uninformed as to the size of blocks or to use varying block sizes. With or without blocking, it is common to use *stratified* randomization. Most frequently, the use of stratification reflects the desire to ensure that there will be between-group balance with respect to some known important risk factor. Thus, if gender is known to be associated with treatment success, stratification by gender can ensure gender balance by using separate blocked randomization schemes for male and female subjects. Other less commonly used randomization schemes include a variety of adaptive methods^[10,11] in which nonconstant randomization probabilities depend partly or fully on the degree of between-group balance that has been achieved in previously randomized subjects. With some adaptive procedures, such as the play-the-winner rule,^[12] randomization probabilities can depend on success rates with previous subjects.

BLINDING

The term *blinding* (or *masking*) refers to the decision to keep subjects and/or investigators uninformed as to treatment assignment as the study progresses. A *single-blind* study is one in which the subject is unaware of his treatment group assignment; a *double-blind* study is one in which neither the subject nor the investigator is provided with this information. In the less commonly used *triple-blind* study, the Data- and Safety-Monitoring Committee (DSMC) is also kept blinded when they evaluate data as the study progresses.

The purpose of blinding is to reduce the likelihood that study assessments will be biased because subject or investigator behavior has been influenced by the knowledge of treatment group assignment. Thus, a subject who knows he has been assigned to a usual care group may be more inclined to drop out or become noncompliant because he would prefer to be in the investigative arm of the trial. Similarly, an investigator who wants to establish the efficacy of a new drug may be influenced in subtle ways when she must make close decisions about ambiguous events if she knows which treatment the subject has received. As is the case with nonrandom or inadequately concealed treatment allocation, the literature suggests that there can be substantial differences between the results of blinded and nonblinded studies. Thus, in a review of 250 controlled clinical trials, Schulz et al.^[7] found that the absence of a double blind was associated with a 17% inflation of the odds ratio that describes the benefit of treatment. Similarly, Colditz et al.^[4] found that RCTs that did not use a double blind were significantly more likely to report a benefit on the new treatment than were double-blind RCTs.

A basic principle of clinical trial conduct is that while blinding is not always feasible, it should not be viewed as an all-or-nothing proposition. Thus, in a medication vs. surgery trial, it is obviously impossible to keep physicians

or subjects blinded as to treatment assignment. However, it may be quite reasonable to insist that the individual who interprets the laboratory test or the CT scan that determines therapeutic success is blinded as to the treatment received by the patient. In general, the goal of every trial should be to maximize the level of blinding within the framework of the limitations that are imposed by practical considerations. Whatever the level of blinding, ethical considerations require that there be a mechanism through which blinding codes can be broken when such action is necessitated by concerns about patient safety.

SELECTION AND ASSESSMENT OF ENDPOINTS

An endpoint in a clinical trial is a parameter that will be compared across the arms of the study in order to evaluate the success of the study treatment. Endpoints should be prospectively and unambiguously defined, quantifiable or categorical measures that correspond precisely to the scientific goals of the trial. Because they are the ultimate determinants of treatment success, every effort should be made to avoid bias in the evaluation of endpoints. Thus, following the suggestion in the “Blinding” section, if the blinding of investigators is not feasible in a given trial, procedures that ensure the blinded evaluation of endpoints should be implemented whenever it is practical to do so. When the endpoint is, e.g., cardiovascular mortality, committees are often set up to provide an unbiased determination of the true cause of death. When endpoints in multicenter trials involve the evaluation of blood samples or of electrocardiograms, it is common to use a centralized reading center for all clinical sites to ensure that determinations are made using the same procedures.

Endpoints in clinical trials are often categorized as primary, secondary, and, sometimes, exploratory. A basic principle of trial design is that there should be a small number of *primary* endpoints that are the defining measures of the success of the study treatment. The primary endpoints are the most important measures of treatment success. The emphasis on a small number of such endpoints reflects concern about the possible effect of multiple-comparison problems, the unavoidable reality that if you have many primary endpoints, the probability that one or more will be significant by chance is increased. If there are many primary endpoints, concerns about multiple comparisons may compromise the most basic conclusions of the study. With one or two primary endpoints, the multiple-comparison problem does not arise.

In many clinical trials, a decision must be made as to whether the primary endpoints should be “true” endpoints or “surrogate” endpoints. Generally speaking, a *true* endpoint is one that has direct clinical relevance to the patient. Examples include mortality, the remission of a cancer, and the successful treatment of a disease. *Surrogate* endpoints are used as a less rigorous alternative to the clinical

endpoint in settings where the clinical endpoint is too difficult, time consuming, or expensive to measure. Such endpoints can only be useful if they are highly associated with the true endpoint of interest. Thus, blood pressure is a potentially viable surrogate for stroke because hypertension is known to be a major risk factor for stroke. For similar reasons, CD4 levels may be a reasonable surrogate for mortality in AIDS patients.

The most important reason for using surrogate endpoints is the potentially large reduction in sample size, trial duration, and cost that they may yield when the true endpoint is infrequent or requires many years to observe. Thus, Wittes et al.^[13] suggest that a trial whose primary endpoint was a reduction in stroke rate might require 5 years of study and 25,000 patients, whereas the same trial using diastolic blood pressure as a surrogate endpoint could be completed in 1–2 years using 200 patients. Unfortunately, this huge sample-size advantage has a large potential downside because there are many predictors of stroke and reducing blood pressure may leave stroke rates unchanged. In the Cardiac Arrhythmia Suppression Trial (CAST^[14,15]), the effect on mortality of three FDA-approved antiarrhythmic drugs were tested in high-risk patients with a history of both myocardial infarction and ventricular ectopy. The logic of CAST was that as these drugs were known to reduce the rate of a major risk factor for cardiac death, they should also reduce death rates. Unfortunately, the exact opposite happened, and two arms of the study were stopped early because of a substantial increase in mortality. Similar problems with surrogate endpoints have been found by meta-analyses that have demonstrated that quinidine is associated with increased mortality although it can control atrial fibrillation^[16] and that lidocaine is associated with both a one-third reduction in ventricular tachycardia and a one-third increase in mortality.^[17,18]

RECRUITMENT PROCEDURES

A vital component of every clinical trial is the expeditious recruitment of a sufficient number of eligible subjects. Because of this, the protocol writing and planning stages of every trial must include a basic feasibility evaluation: Are we capable of recruiting the required number of subjects? The answer to this practical question can be a driving force in determining eligibility and exclusion criteria. In some cases, it can force a modification of the scientific goals of a study. In the worst case, it can lead to the conclusion that a proposed study should not be attempted. When recruitment is slower than anticipated, the cost of an already expensive process goes up, investigators may lose interest, study quality may deteriorate, and there is an incentive to randomize subjects whose eligibility may be questionable. If delays are sufficiently prolonged, the scientific questions that motivated the study may diminish in importance or become moot. Finally, it is always possible

that a study may have to be stopped early because of inadequate recruitment.

In spite of, and perhaps because of, its importance, there is a natural tendency to overestimate recruitment capabilities. This is especially true because no clinic will be invited to participate in a multicenter trial if it cannot justify its ability to enroll some minimum required number of subjects. The tendency toward overestimation is emphasized in a comprehensive review of the recruitment literature by Hunninghake et al.,^[19] who asserted that “it is extremely rare for a study to enroll the required number of participants within the time frame originally designated.” This observation is highlighted by an evaluation of recruitment success in seven multicenter clinical trials sponsored by the Veterans Administration.^[20] This review found that one trial was stopped early because of inadequate recruitment, while the remaining six required more time than was initially planned to reach recruitment targets.

The potential magnitude of the recruitment burden is illustrated by large multicenter trials such as the Lipid Research Clinics Primary Prevention Trial^[21] and the Systolic Hypertension in the Elderly Program.^[22] In both of these studies, it was necessary to screen several hundred thousand subjects because both trials were such that approximately 100 subjects had to be screened in order to find a single subject who was ultimately randomized. While screened to eligible ratios of 100 or more are not typical, these examples provide ample evidence that a realistic and prospective appraisal of recruitment capabilities is vital in every clinical trial. They also emphasize the fact that the mundane details of the recruitment process may sometimes deserve as much attention as do the more glamorous scientific concerns of a trial. The many standard approaches to recruiting subjects for clinical trials include direct contact at clinics; public screenings for conditions such as hypertension, diabetes, and hypercholesterolemia; mailings and phone calls to subjects who are known to have a given disease; referrals from private physicians and primary care clinics; retrospective chart reviews, an approach that may be the only option when diseases are rare; and television and radio advertisements. The strengths and weaknesses of these and other approaches to recruitment are discussed by Meinert.^[23]

LOSS TO FOLLOW-UP

A fundamental objective of every well-conducted RCT is to minimize the rate at which subjects are lost to follow-up. If loss to follow-up occurs in a purely random fashion and to the same degree in each arm of the study, it may be associated with a loss of statistical power because of the reduced sample size, but it is unlikely to be an important source of bias. However, even when the apparent reason for loss to follow-up is benign, the impact on study results may be substantial. For example, patients may terminate

their involvement in a study because they have moved out of town or because their level of frailty makes it difficult for them to get to the clinic. While these behaviors are likely to be balanced across groups in a randomized study, they may compromise the generalizability of results by excluding too many of the sickest patients or a preponderance of older patients who have moved away when they retired. More serious consequences may result if the reasons for loss to follow-up are associated with characteristics of the treatment. Thus, the Coronary Drug Project (CDP) Research Group^[24] found that loss to follow-up was greatest in the treatment arm that also had the largest number of drug-related adverse events. In the Lipid Research Clinics Coronary Primary Prevention Trial,^[25] the somewhat different problem was that treatment side effects led to worse compliance in the treatment group than in the placebo group.^[26] In a more recent RCT involving the treatment of AIDS patients,^[27] it was reported that loss to follow-up was significantly associated with several measures of disease progression. The authors concluded that “losses to follow-up probably decreased substantially the observed number of primary endpoints, curtailed the power of the trial to demonstrate any difference between immediate and deferred initiation of antiretroviral therapy, and may have introduced large bias in the estimated hazard ratio for the primary endpoint and its statistical significance.”

There are many standard approaches to encouraging clinical trial participants to remain in a study and to attend required follow-up visits. These include providing routine conveniences such as flexible appointment schedules, limiting waiting times, and easy clinic access; regular contacts with subjects between visits; acknowledging special occasions such as patient birthdays and Christmas; payment of parking and travel fees associated with the study and, sometimes, paying the subject for his willingness to participate; and keeping the subject informed of the details of the protocol and of the scientific importance of his contribution as a participant.

It is often the case that loss to follow-up is associated with subjects who relocate. When investigators are not directly informed of the new address, simple steps, such as contacting friends, relatives, and employers, or getting address change information from the post office, are likely to be helpful. When the new address is known and when the study is multicenter, it is often feasible to see the subject at another study clinic. Alternatively, subjects who relocate can sometimes be seen when they return for visits to their former city of residence by enlisting and paying colleagues who live in the city to which a subject moves, or by having study personnel see the subject when they are in the vicinity of a subject's new residence. If a subject is lost to follow-up in a study where the primary endpoint is mortality, the National Death Index can serve as a valuable resource for determining with a high degree of confidence whether or not the subject has died. The fact that these

somewhat extreme measures are not uncommon highlights the importance attached to maximizing follow-up rates.

MULTICENTER TRIALS

Multicenter clinical trials are trials that enrol patients from more than one clinical site. They are generally used because the required sample size is too large for the trial to be feasible using only one clinical site, or because the use of a single site would mean that it would take an excessive period of time to complete the study. The primary challenge of multicenter trials is found in the organizational complexity that is necessary to ensure that the protocol is followed in a uniform way at the geographically distant participating clinics. At the top of the trial organization is the study chair, who has the primary executive responsibility for the trial and who is chair of the executive committee. In addition to the study chair, executive committee members will generally include the principal investigator at all resource centers along with other individuals from within and without the trial who have expertise that will facilitate the scientific goals or practical conduct of the trial. The executive committee has overall day-to-day decision-making responsibility for the trial. Its specific responsibilities include maintaining the scientific integrity of the trial; preparing or overseeing the preparation of a manual of procedures and other study documents; appointing subcommittees that are responsible for tasks that include writing manuscripts, verifying endpoints, and codifying publication policies; overseeing the development of study forms; reviewing study manuscripts prior to submission; responding to concerns about clinics that may be having difficulty with enrolment or other trial activities; setting priorities for the study; and having the basic responsibility for the design and conduct of the trial.

The conduct of every multicenter trial is facilitated by one or more resource centers. The one such center that is integral to the functioning of every multicenter trial is the CC. The CC has a broad range of responsibilities that cover all phases of the trial. During the protocol development stage, the focus of the CC is on questions of sample size and statistical power, the scientific integrity of the proposed study design, a data analysis plan, and the development of data-processing and quality control procedures. When patients are being recruited and followed up, the CC is focused on such activities as the day-to-day processing and quality control of data; regular communication with the clinical sites so as to ensure the completeness and accuracy of the data they provide; discussing quality control problems with clinical sites and with the executive committee; and preparing reports that measure the progress of the trial through clinic-specific and studywide statistics on recruitment rates, follow-up rates, error rates on forms, missed patient visits, and other measures of study progress. In many multicenter trials, the CC will also be involved in

activities that include site visits to the clinics; designing, modifying, and disseminating study forms; and training clinic personnel in assessment procedures. When the enrolment and follow-up of subjects have been completed, the activities of the CC are redirected toward the analysis of data, extensive collaboration in the preparation of manuscripts, and archiving the data generated by the study.

In addition to a CC, most multicenter clinical trials have resource centers that include reading centers and central laboratories. These are centralized facilities whose purpose is to ensure the uniform interpretation of laboratory and clinical data. They tend to be used when the parameter of interest is critical to the trial and when the complexity or lack of standardization of the assessment suggests that local evaluations would be: (1) impossible because the expertise or equipment is not available at some sites, or (2) difficult to standardize because of the inherent characteristics of the assay.

An additional organizational component of most multicenter clinical trials is the *DSMC*. This committee contains outside experts who are recommended by the executive committee and, in general, appointed by the funding agency. The primary purpose of the DSMC is to provide independent oversight and advice regarding all major study activities. It meets periodically with the executive committee to evaluate interim data, to assess the progress of the study as measured in reports prepared by the CC and the reading centers, and to review the ethical conduct of the study. It is frequently responsible for providing external review of the resource center and for providing advice as to whether poorly functional clinical centers should be dropped from the study or placed on probation. Following its periodic reviews of interim data, the DSMC may recommend changes in the study protocol such as an increase in the sample size. In more extreme settings, it may suggest the termination of the study because of treatment side effects or because of inadequate response to study treatment.

INTERIM DATA ANALYSES

A common feature of many clinical trials is the interim data analysis. An *interim* analysis is an evaluation of the data while patient recruitment or follow-up is still progressing. The purpose of these analyses is to determine whether early trends in the data suggest the need to modify the study protocol. Such modifications may take many forms. For example, an interim analysis may suggest that a modification of the dosing schedule is necessary because of excessive toxicity. The Cardiac Arrhythmia Suppression Trial^[14,15] provides a more extreme illustration of the potential impact of an interim analysis. In this trial, the interim data resulted in the termination of the encainide and flecainide arms of the study because the data suggested increased mortality with these two drugs. A clinical trial (or an arm of the trial) may

also be terminated if an interim analysis suggests that the treatment is ineffective and that there is no hope of ever achieving statistical significance, or, as happened with the aspirin arm of the Physicians Health Study,^[28] that the treatment is so clearly effective that it would be unethical to continue to assign subjects to the placebo group. If the interim data suggest that between-group differences in primary outcome measures are smaller than was anticipated in the original sample-size computations, the conclusion may be that the target sample size should be increased. Because interim analyses are concerned with such basic issues as toxicity and the continued use of a placebo when existing data may have established the efficacy of the treatment, such analyses are viewed by many investigators as a being moral imperative.

In a single-center trial, interim analyses are ordinarily conducted by the study statistician. In multicenter trials, these analyses are conducted by the CC, often with active input from the DSMC, the committee responsible for making recommendations in response to the interim report. Results of the interim analysis are presented by the executive committee to the DSMC. However, because of concerns about blinding, it is sometimes the case that these results can be seen only by the DSMC, the principal investigator of the CC, and the representative of the funding agency. Thus, meetings about interim reports are sometimes conducted after the chair of the executive committee and the directors of the reading centers have been asked to leave the room. In single-center trials, the ideal committee structure may not exist, and it may be necessary to devise more ad hoc approaches to ensure that investigators who recruit or evaluate patients are not aware of the contents of the interim reports.

A statistical concern that arises naturally in trials that contain interim data analyses is the multiple-look problem. The *multiple-look* problem reflects the fact that the possible early termination of a study, because of results from interim looks at the data are significant, increases the likelihood that significant results will be achieved when the null hypothesis is true.^[29,30] Thus, if the type I error is supposed to be 0.05 and if you may stop the study early because an interim analysis produced a *p*-value of less than 0.05, the repeated opportunities to claim significance artificially inflate the type I error. That is, the true probability of claiming significance when the null hypothesis is true is greater than 0.05. In order to address this problem, a variety of “group sequential” testing procedures have been developed. While we do not discuss the details in this article, all of these group sequential procedures have a common theme. Using some formal statistical mechanism, the “nominal” *p*-value that is necessary to establish significance when the various data analyses are conducted is reduced to something less than 0.05. The precise nominal *p*-values are defined by the desire to ensure that the true type I error is 0.05. To accomplish this task, the sum of the probabilities of claiming significance at all analyses

combined must be exactly 0.05, when the null hypothesis is true. For details on specific group sequential testing procedures, we refer the reader to the methods developed by Pocock,^[31] O’Brien and Fleming,^[32] and Lan and DeMets.^[33] An excellent general review of these methods is provided by Geller and Pocock.^[34]

WHO GETS ANALYZED?

Protocol violations are an unavoidable feature of most clinical trials. Subjects may drop out of the study early, miss follow-up visits, cross over to a different arm of the study, or, otherwise, be noncompliant with the prescribed therapeutic regimen. The investigator may be the source of the protocol violation when assessment schedules or procedures are not followed and when randomized subjects are ineligible or, as sometimes happens, do not have the disease in question. When protocol violations occur, there can be a powerful incentive to exclude the relevant patients when data are analyzed. After all, the thinking goes, why evaluate a treatment using patients who may have received only a small portion of the prescribed medication?

While this logic has an intuitive appeal, there is ample evidence that in many circumstances, subjects who are excluded from data analyses because of protocol violations will be a source of biased results. The problem with excluding protocol violators is that subjects who violate the protocol may be fundamentally different from those who are fully compliant in the way they respond to treatment, or, in particular, the protocol violation may be partly or entirely a result of the study intervention itself. For these and other reasons, the broadly accepted view is that the intention-to-treat (ITT) principle should govern the primary analyses of clinical trials data unless there is a strong reason to believe that bias will not result from some alternative type of analysis.^[35-37] When ITT is used for the primary analysis, it is sometimes considered appropriate to perform some exploratory analyses using subgroups as long as the reader has been clearly cautioned about the potential limitations of violating the ITT principle.

There are many illustrations of the bias that can result from excluding patients from data analyses. For example, in trials aimed at reducing infarct size in patients with acute myocardial infarction, it is essential to include patients in whom an infarct was ruled out because the infarct size was measured as zero. If you exclude such patients, you may be excluding precisely the patients in whom the treatment was most effective, the ones in whom all myocardium was salvaged by the treatment. More typical are the examples of the potential impact of excluding poor compliers. In the CDP,^[38] the mortality rate in compliant clofibrate patients was 15.7% as compared to a much higher 24.6% in noncompliant clofibrate patients. The drug appears to be effective until you discover that compliance to placebo was associated with an even larger apparent “treatment”

benefit. The problem is that CDP compliers were fundamentally different from CDP noncompliers because the compliers were more likely to engage in heart-healthy behaviors or, otherwise, more likely to have an improved outcome. If the CDP investigators had excluded poor compliers, they would have been analyzing a cohort of patients fundamentally different from the patients who had been randomized in the first place.

GOOD CLINICAL PRACTICE

Good clinical practice (GCP) is usually referred to as a set of standards for clinical trials to achieve and maintain high-quality clinical research in a sensible and responsible manner.^[39] In essence, GCP deals with patients' protection and the quality of data used to prove the efficacy and safety of a drug product. GCP ensures that all data, information, and documents related to clinical trials can be confirmed as being properly generated, recorded, and reported through the institution by independent audits.

CONCLUSION

The randomized clinical trial is broadly viewed as the gold standard approach to clinical research aimed at comparing the efficacy of two or more interventions. The key advantage of randomization is that it is likely to yield between group balance with respect to both known and unknown risk factors, a circumstance that is far less likely using other approaches to clinical research. But the results of a randomized trial may be severely compromised by poor research practice. Thus, results can be biased by the absence of blinding, by excessive dropout and by different rates of dropout in the study groups, or by inappropriate data analytic decisions regarding the use of intention-to-treat. The interpretation of trial results can also be compromised by an inappropriate selection of primary endpoints and the loss of focus that comes from selecting too many endpoints, by inadequate recruitment procedures that yield too few subjects and uncertain conclusions, and by poor quality control in multicenter investigations. Careful attention to the details of the design and conduct of clinical trials is essential if results and conclusions are to be accepted by the research community.

Clinical Trials: Controversial Issues

Shein-Chung Chow

Center for Food and Drug Inspection, China Food and Drug Administration, Beijing, China

Abstract

In clinical development of a test treatment under investigation, clinical trials are often conducted for the evaluation of safety and efficacy of the test treatment. To provide an accurate and reliable assessment of the test treatment under study, adequate and well-controlled clinical trials using valid study design are necessarily conducted for obtaining substantial evidence of the safety and efficacy of the test treatment under investigation. In practice, however, some debatable issues are commonly encountered regardless of the compliance of Good Statistics Practice (GSP) and Good Clinical Practice (GCP). These issues include, but are not limited to, (1) appropriateness of statistical hypotheses for clinical investigation, (2) instability of power calculation for sample size determination, (3) integrity of randomization and blinding, (4) clinical strategy for endpoint selection, (5) impact and sensitivity of protocol amendments, (6) controversial issue of multiplicity in clinical trials, (7) validity and power of missing data imputation, (8) flexibility and feasibility for the use of adaptive design methods, and (9) challenge of the independence of data monitoring committee (DMC). In this article, these issues are briefly described. The impact of these issues on the evaluation of the safety and efficacy of the test treatment under investigation is discussed with examples whenever applicable. Some recommendations regarding possible resolutions of these issues are also provided.

Keywords: Data safety monitoring committee; Endpoint selection; Integrity of blinding; Missing data imputation; Multiplicity; Protocol amendment; Two-stage adaptive designs.

INTRODUCTION

In clinical research and development of a test treatment, relevant clinical data are usually collected from subjects with the diseases under study in order to evaluate the safety and efficacy of the test treatment under investigation. To provide an accurate and reliable assessment, adequate well-controlled clinical trials using valid study designs are necessarily conducted for obtaining substantial evidence of the safety and efficacy of the test treatment under investigation. Clinical trial process, which consists of protocol development, trial conduct, data collection, statistical analysis/interpretation, and reporting, is a lengthy and costly process. This process is necessary to ensure a fair and reliable assessment of the test treatment under investigation. In practice, some controversial or debatable issues inevitably occur regardless of the compliance of Good Statistics Practice (GSP) and Good Clinical Practice (GCP). Controversial issues in clinical research are defined as debatable issues that are commonly encountered during the conduct of clinical trials (see, e.g., the works of Chow,^[1] Chow et al.,^[9] and Chow and Song^[10]). In practice, debatable issues could be raised from (1) compromises between theoretical and real

practices; (2) miscommunication, misunderstanding, and/or interpretation in perception among regulatory agencies, clinical scientists, and biostatisticians; and (3) disagreement, inconsistency, and errors in clinical practice.

In clinical research and development of a test treatment under investigation, commonly seen controversial issues include, but are not limited to, (1) appropriateness of traditional statistical hypotheses for clinical evaluation of *both* safety and efficacy, (2) correctness of power analysis for sample size calculation based on the information from a small-scale pilot study, (3) integrity of randomization and blinding for preventing potential biases, (4) post hoc endpoint selection (based on some derived endpoints), (5) impact of protocol amendments on the characteristics of the trial population, (6) multiplicity in clinical trials, (7) missing data imputation, (8) adaptive design methods, and (9) independence of the data monitoring committee (DMC).

In this article, we will review these debatable issues rather than provide resolutions. The impact of these issues on the evaluation of the safety and efficacy of the test treatment under investigation is discussed with examples whenever applicable. Recommendations regarding possible

resolutions of these issues are also provided whenever possible. It is our goal that medical/statistical reviewers from regulatory agencies such as the US Food and Drug Administration (FDA), clinical scientists, and biostatisticians will (1) pay attention to these issues, (2) identify the possible causes of these debatable issues, (3) resolve/correct the issues, and consequently (4) enhance GSP and GCP for achieving the study objectives of the intended clinical trials.

APPROPRIATE HYPOTHESES FOR CLINICAL INVESTIGATION

In clinical trials for the evaluation of safety and efficacy of a test treatment under investigation, a typical approach is to first test for the null hypothesis of no treatment difference in *efficacy* based on clinical data collected under a valid trial design. The rejection of the null hypothesis would lead to favor the alternative hypothesis that there is a difference. If there is a sufficient power for correctly detecting a clinically meaningful difference (improvement) when such a difference truly exists, we claim that the test treatment is efficacious. The test treatment will then be reviewed and approved by the regulatory agency such as the FDA if the test treatment is well tolerated and there appears no safety concern.

In practice, however, it is a concern whether the traditional approach based on hypothesis testing on efficacy alone (i.e., the study is powered based on the efficacy alone) for the evaluation of *both* safety and efficacy of a test treatment under investigation is appropriate. The test treatment may be approved by the regulatory agency based on the hypothesis testing on efficacy alone and subsequently may get withdrawn due to safety concerns. A typical example is the withdrawal of Vioxx. Vioxx is a COX-2 inhibitor drug intended for treating arthritis approved by the FDA in 1999, which was subsequently withdrawn from the market in 2004 due to the safety concern of increased risk of heart attack and stroke.

To overcome this problem, alternatively, Chow^[1] suggested that both safety and efficacy should be included in a composite hypothesis for testing the clinical benefit of the test treatment under investigation. Composite hypotheses, which take both safety and efficacy into consideration, are summarized in Table 1.

As it can be seen from the table, as an example, suppose that we are interested in demonstrating therapeutic superiority in efficacy and equivalence in safety. In this case, we may consider testing the composite null hypothesis that H_0 : not *SE*, where *S* denotes superiority in efficacy and *E* indicates equivalence in safety. Thus, we would reject the null hypothesis in favor of the alternative hypothesis that H_0 : *SE*. In other words, the test treatment is superior to the active control agent and its safety appears to be equivalent to the active control agent. To test the null hypothesis that

Table 1 Composite hypotheses for clinical investigation

Efficacy	Safety		
	N	S	E
N	NN	NS	NE
S	SN	SS	SE
E	EN	ES	EE

N = Non-inferiority; S = superiority; E = equivalence.

H_0 : not *SE*, appropriate statistical tests should be derived under the null hypothesis. Under the alternative hypothesis, the power of the test statistic can then be evaluated and appropriate sample size can be selected for achieving a desired power.

Switching from a single hypothesis testing (traditional approach based on efficacy alone) to a composite hypothesis testing (based on both efficacy and safety), an increase of the sample size is expected. In the interest of controlling the overall type I error rate at the α level, in composite hypothesis testing, appropriate α levels (say α_1 for efficacy and α_2 for safety) may be chosen.

INSTABILITY OF SAMPLE SIZE CALCULATION

In clinical trials, power analysis for sample size calculation (or power calculation) is necessarily performed to ensure that there is high probability of correctly detecting a clinically meaningful effect size if such an effect size truly exists. In practice, power calculation is often performed based on (1) the information obtained from previous studies or pilot studies, (2) the information from literature, or (3) the investigator's guess or belief with or without scientific justification. Since a pilot study is usually a small-scale study with limited number of subjects, the data obtained from the pilot study and/or the investigator's guess or belief could be deviated far from the truth, which will bias the assumptions made for power calculation for the sample size. Thus, it is a concern whether sample size calculation based on the information from the pilot study or the investigator's guess or belief is robust or stable.

Chow et al.^[8] studied the instability of power calculation for sample size in terms of its asymptotic bias. For simplicity and illustration purposes, consider the simple case for testing the equality of treatment effect where the primary endpoint is a continuous normal variable. In other words, consider testing the following null hypothesis:

$$H_0 : \mu_T - \mu_C = \delta = 0,$$

where μ_T and μ_C are the means for a test treatment and a (placebo) control, respectively, and δ is a clinically meaningful difference or effect size. Power calculation leads to the following formula for the required sample size per

arm, assuming that $N_T = N_C = N_0$ (see also the work of Chow et al.^[8]):

$$N_0 = \frac{2(z_{\alpha/2} + z_\beta)^2 \sigma^2}{\delta^2},$$

where α and β are the probabilities of committing type I error and type II error, respectively, and σ is the standard deviation of the control. In practice, δ and σ^2 are often estimated by the difference in sample mean ($\hat{\delta} = \hat{\mu}_T - \hat{\mu}_C$) and sample variance (s^2). In other words, σ^2/δ^2 is estimated by $s^2/\hat{\delta}^2$. It can be verified that the leading asymptotic bias term of $E(\hat{\theta} = s^2/\hat{\delta}^2)$ is given by

$$E(\hat{\theta}) - \theta = \frac{3\theta^2}{N_0} \{1 + o(1)\}.$$

Table 2 provides the biases of $\hat{\theta} = s^2/\hat{\delta}^2$ in sample size calculation with various combinations of δ , σ , and θ . As can be seen from the table, the sample size calculation based on the estimates from a small-scale pilot study could be very misleading especially when there is a large variability associated with the observed data. Thus, it is a concern that the estimate of effect size and standard deviation based on a pilot study is often imprecise.

The above discussion justifies that there is a need for sample size reestimation or sample size adjustment during the conduct of clinical trials especially when the underlying assumptions are not met based on the review of accumulated data at interim. Sample size reestimation is often planned in clinical trials utilizing group sequential design with planned interim analyses. In practice, the following sample size adjustment based on the ratio of the initial estimated effect size (E_0) to the observed effect size (E) is usually considered:^[5]

$$N = \min \left\{ N_{\max}, \max \left(N_{\min}, \text{sign}(E_0 E) \left| \frac{E_0}{E} \right|^a N_0 \right) \right\},$$

where N is the sample size after adjustment; $N_{\max}$ and $N_{\min}$ are the maximum (e.g., due to financial and/or other constraints) and minimum (e.g., the sample size for the interim analysis) sample sizes; a is a constant (usually determined based on the review of the interim analysis results), and $\text{sign}(x) = 1$ for $x > 0$; otherwise $\text{sign}(x) = -1$.

Table 2 Biases of sample sizes

δ	σ	$\theta = \sigma^2/\delta^2$	Classic sample	Sample size	
			size N_0	Bias $3\theta^2/N_0$	with bias N
5	10	4	32	1.53	44
	20	16	126	6.12	174
	30	36	283	13.76	391
10	10	1	8	0.38	11
	20	4	32	1.53	44
	30	9	71	3.44	98

Note that the above sample size adjustment reduces to the method proposed by FDA statisticians for normal study endpoint with $a = 2$.

It, however, should be noted that the information obtained for sample size reestimation at interim is still an estimate of the treatment effect. Thus, the instability issue regarding the sample size remains unsolved because there is a variability associated with the observed (estimated) treatment effect at interim.

INTEGRITY OF RANDOMIZATION/BLINDING

In clinical trials, randomization and blinding (e.g., double-blind) are often employed to prevent or minimize the bias (e.g., operational bias) from the assessment of a test treatment under investigation. In randomized and double-blind clinical trials, due to human nature, both patients and the investigator may guess what treatment the patients are receiving. Karlowski et al.^[14] challenged the integrity of the use of randomization and blinding in a randomized, double-blind, placebo-controlled study conducted by the National Institutes of Health. The study was to evaluate the difference between the prophylactic and therapeutic effects of ascorbic acid for the common cold.^[6] After the completion of the study, a questionnaire regarding the knowledge of the treatment assignment was distributed to every subject enrolled in the study (a total of 190 subjects completed the study). Results from the 190 subjects are summarized in Table 3.

The table indicates that there is a high percentage of patients who correctly guessed the treatment assignment they received. Thus, there is a reasonable doubt that the blindness may not be preserved during the study. Thus, “How to test for the integrity of blinding in clinical trials?” is an interesting question.

To address this question, according to Table 3, Chow and Shao^[5] proposed a test for testing the integrity of blinding.^[7] Without loss of generality, consider a parallel design comparing $a \geq 2$ treatments conducted at a single study site. Let A_{ij} be the event that a patient in the j th treatment group who guesses that he/she is in the i th group, $i = 1, \dots, a, a + 1$, where $i = a + 1$ defines the event that a patient whose answer is “do not know” or “does not guess.” Consider the following null hypothesis:

$$H_0 : P(A_{ij}) = P(A_{i1}) \text{ for any } i \text{ and } j.$$

Table 3 Results of patients’ guesses

Patient’s guess	Actual treatment assignment	
	Treatment	Placebo
Treatment	40 (39.6%)	11 (12.4%)
Placebo	12 (11.9%)	39 (43.8%)
Did not respond	49 (48.5%)	39 (43.8%)
Total	101	89

If the above null hypothesis holds, then we claim that the blindness is preserved. Chow and Shao^[5] indicated that H_0 can be tested using the Pearson's chi-square test under the contingency tables constructed based on the observed counts given in Table 3. As a result, a simple calculation gives Pearson's chi-square statistic of 31.3. Thus, the null hypothesis of independence is rejected (p -value < 0.001). Thus, we conclude that the blindness is not preserved and the integrity of blinding is in doubt.

When the integrity of blinding is doubtful, it is suggested that an appropriate adjustment to statistical analysis should be made. In practice, one of the debatable issues is that whether a formal statistical test for the integrity of the blinding should be performed at the end of the clinical trial, although the results are positive or negative. If the results are positive, the sponsor would prefer not to perform the test. However, if the results are negative, the sponsor would argue to perform the test and hopefully to rescue the failed trial. In addition, what action should be taken if a positive clinical trial fails to pass the test for the integrity of the blinding?

CLINICAL STRATEGY FOR ENDPOINT SELECTION

In clinical trials, it is not uncommon to see that we may reach some clinical endpoints but fail to achieve other clinical endpoints. In this case, the selection of clinical endpoint plays an important role for achieving the study objectives with a desired power at a prespecified level of significance. For a given primary clinical endpoint, power calculation and statistical analysis are usually performed based on either the absolute change from baseline or the relative (or percentage) change from baseline. The absolute change from baseline and the relative change from baseline are referred to as derived study endpoints. Based on the original data obtained from the same target patient population, another derived endpoint based on the percentage of patients who show some improvement is often considered. A subject who shows some improvement is considered a responder. The definition of a responder, however, could be based on either the absolute change from baseline or the relative change from baseline of the primary study endpoint.

It should be noted that statistical analysis/interpretation, sample size calculation, and power for different derived

study endpoints are different. Thus, endpoint selection has become very controversial especially when a significant result is observed based on a derived endpoint but not on the other derived endpoints. For example, in a weight reduction study with obesity patient population, statistical analysis based on the absolute change from baseline is often different from that based on the relative (percentage) change from baseline. Besides, power analysis for sample size calculation based on the absolute and relative changes could be very different depending upon what difference is considered of clinical importance. For example, the sample size required in order to achieve the desired power based on the absolute change could be very different from that obtained based on the percentage change, or the percentage of patients who show an improvement based on the absolute change or relative change at α level of significance.

The issue could become more complicated if the intended trial is a non-inferiority trial for establishing non-inferiority of a test treatment to an active control agent. In this case, sample size calculation will also depend upon the selection of non-inferiority margin. Similar to the endpoint selection based on either the absolute change or the relative change, non-inferiority margin could be selected based on either the absolute change or the relative change. As a result, there are eight possible clinical strategies with different combinations of derived study endpoints (i.e., absolute change, relative change, responder analysis with absolute change, and responder analysis with relative change) and non-inferiority margin (absolute change and relative change) for the assessment of the treatment effect (Table 4). To ensure the success of the intended clinical trial, the sponsor will usually carefully evaluate the eight clinical strategies through extensive clinical trial simulation for selecting the most appropriate (derived) endpoint, clinically meaningful difference, and non-inferiority margin during the planning stage of protocol development.

In practice, some clinical strategies may be successful in achieving study objectives with desired power, whereas some strategies may not. These inconsistent results are debatable. The sponsors may choose the strategy to their best interest, whereas the FDA may challenge the sponsors regarding the inconsistent results. In other words, the FDA may ask the sponsors to address the questions that answer (1) which endpoint is telling the truth? and (2) can these study endpoints translate one another since they are derived based on the data collected from the same patient population?

Table 4 Clinical strategy for endpoint selection in non-inferiority trial

Study endpoint	Non-inferiority margin	
	Absolute difference (δ_1)	Relative difference (δ_2)
Absolute change (E_1)	$E_1\delta_1$	$E_1\delta_2$
Relative change (E_2)	$E_2\delta_1$	$E_2\delta_2$
Responder based on absolute change (E_3)	$E_3\delta_1$	$E_3\delta_2$
Responder based on relative change (E_4)	$E_4\delta_1$	$E_4\delta_2$

IMPACT AND SENSITIVITY OF PROTOCOL AMENDMENTS

In clinical trials, protocol amendments are commonly issued after the initiation of a clinical trial due to various reasons such as slow enrollment and/or safety concerns. In practice, before a protocol amendment can be issued, detailed description, rationales, and clinical/statistical justification regarding the changes must be provided to ensure the validity and integrity of the clinical trial. Statistically, it is often a concern that major or significant changes or modifications to study protocol could result in a similar but different patient population. For example, if major or significant changes are made to eligibility (inclusion/exclusion) criteria of the study, the original target patient population may have become a similar but different patient population. This raises the debatable issue regarding the validity and reliability of the statistical inference to be drawn based on the data collected before and after protocol amendment.

To evaluate whether major or significant changes made to the original target patient population have resulted in a similar but different target patient population after the implementation of protocol amendments, denote the original target patient population by (μ, σ) . Also, denote the resultant (actual) patient population after the implementation of a protocol amendment by (μ_1, σ_1) , where $\mu_1 = \mu + \varepsilon$ and $\sigma_1 = C\sigma$ ($C > 0$). The shift in treatment effect of the original target patient population can be characterized by

$$E_1 = \left| \frac{\mu_1}{\sigma_1} \right| = \left| \frac{\mu + \varepsilon}{C\sigma} \right| = |\Delta| \left| \frac{\mu}{\sigma} \right| = |\Delta| E,$$

where E and E_1 are the effect sizes before and after population shift, respectively, and $\Delta = (1 + \varepsilon/\mu)/C$, which is a sensitivity index measuring the change in effect size between the original target patient population and the actual patient population (see, e.g., the works of Chow et al.^[7] and Chow and Shao^[6]). Table 5 provides an evaluation of the impact of protocol amendment in terms of sensitivity index under various scenarios of location shift (i.e., change in ε) and scale shift (change in C). As it can be seen from the table, with the shifts in ε and C (inflation or deflation), the sensitivity index Δ varies from 0.667 to 1.500. It should also be noted that the shift in ε could be offset by the shift in C .

If there is evidence that the mean response is correlated to some covariates, Chow et al.^[3] proposed an alternative approach by considering a model that links the population means and the covariates. In many cases, however, such covariates may not be observable or may not even exist. In this case, Chow et al. approach is not applicable. Alternatively, it is suggested that the sensitivity index Δ be assessed by assuming that there are random shifts in both location and/or scale parameters.

In practice, it is not uncommon to have a number of protocol amendments after the initiation of a clinical trial.

Table 5 Evaluation of sensitivity index

ε/μ (%)	Increase in variability		Decrease in variability	
	C (%)	Δ	C (%)	Δ
-20	100	0.800	—	—
	120	0.667	80	1.000
-10	100	0.900	—	—
	120	0.750	80	1.125
-5	100	0.950	—	—
	120	0.792	80	1.188
0	100	1.000	—	—
	120	0.833	80	1.250
5	100	1.050	—	—
	120	0.875	80	1.313
10	100	1.100	—	—
	120	0.917	80	1.375
20	100	1.200	—	—
	120	1.000	80	1.500

Frequent issuance of protocol amendments may result in a shift in target patient population. Thus, regulatory guidance or regulations on (1) the levels of changes and (2) the number of protocol amendments that are allowed are necessarily developed for maintaining the validity and integrity of the intended study.

MULTIPLICITY IN CLINICAL TRIALS

In clinical trials, multiplicity in clinical trials is usually referred to as multiple inferences that are made simultaneously. The concept of multiplicity could include the comparison of (1) multiple doses (treatments), (2) multiple endpoints, (3) multiple time points, (4) multiple interim analyses, (5) multiple tests of the sample hypothesis, (6) variable/model selection, and (7) subgroup analyses. In practice, it is of interest to the investigators when adjustment for multiplicity should be performed for controlling the overall type I error rate at a prespecified level of significance.

To address this issue, the International Conference on Harmonization (ICH) published a guideline on “Statistical Principles in Clinical Trials” in 1998. This guideline indicates the multiplicity issue for providing substantial evidence in clinical trials. The ICH guideline suggests that data analysis of the clinical trial may necessarily adjust for controlling the overall type I error rate. Moreover, the guideline requires that any adjustment procedure or an explanation (justification) regarding why adjustment is not done be described in detail in the statistical analysis plan. Similarly, the issue of multiplicity is also addressed in the European Agency for the Evaluation of Medicinal

Products (EMA). In 2007, the Committee for Proprietary Medicinal Products published a draft guidance “Points to Consider on Multiplicity Issues in Clinical Trials.” This guidance points out that multiplicity can have a substantial influence on the false positive rate when there is an opportunity to select the most favorable results from two or more analyses. Both the EMA guideline and the ICH guideline recommend stating details of the multiple comparisons procedure in the statistical analysis plan.

In their review article, Westfall and Bretz^[19] indicated that the following are the most commonly seen controversial issues regarding multiplicity in clinical trials:

1. Penalizing for doing more
2. Adjusting α for all possible tests in the trial
3. Testing for family of hypotheses

Penalizing for doing a good job is referred to as the adjustment for multiplicity in dose-finding trials, which often involve several dose groups. For adjusting α for all possible tests, it is overkill to control the α at the pre-specified level because it is not the study objective to show that all of the observed differences (simultaneously) are not by chance alone. In clinical trials, it is debatable for choosing an appropriate family of hypotheses (e.g., primary and secondary study endpoints) for multiplicity adjustment of clinical investigation of the test treatment under study.

Although ICH and EMA did provide some guidance for adjustment of multiplicity, regulations regarding multiplicity adjustment are still not clear. Marcus et al.^[16] indicated that there is no need for multiplicity adjustment for closed testing procedure. Chow^[1] pointed out that one should always check the primary null hypotheses that the trial is powered to test before deciding whether there is a need for multiplicity adjustment.

VALIDITY OF MISSING DATA IMPUTATION

Missing data inevitably occur in clinical trials. When there are a few missing values, one of the approaches is to impute the missing values with their estimates under some valid and appropriate statistical models. Missing data imputation then becomes one of the most debatable issues in clinical trials. The following questions are often asked when there are missing values in clinical trials:

1. Why impute missing values?
2. What methods should be used if we are to impute the missing values?
3. What if when there are a high percentage of missing values?

For the first question, some clinical scientists criticize that missing data imputation actually makes up the data we do not observe. We should not make up data for missing

data as missing data imputation could bias the assessment of treatment effect, and hence missing data imputation does not add much value to the clinical research. For the second question, the method of last observation carried forward (LOCF) is widely used although it has been recognized that the validity of LOCF is questionable. In addition to the method of LOCF, other methods such as the mixed-effects model for repeated measures, generalized estimating equations, and complete case analysis of covariance are often employed in missing data imputation. When there is large proportion of missing values, it is suggested that missing data imputation not be applied. This, however, raises a debatable issue for the determination of the cutoff value for the proportion of missing values for preserving good statistical properties of the statistical inference derived based on the incomplete data set and imputed (complete) data set.

Statistically, one of the concerns for missing data imputation is the potential reduction of power. In clinical trials, it is recognized that missing data imputation may inflate variability due to additional variability associated with the imputed missing data. The inflation of variability will definitely decrease the power. Consequently, the intended clinical trial will not be able to address the scientific/clinical questions asked with desired power. This could be a major concern for regulatory review and approval.

Soon^[18] indicated that management of missing data involves missing data prevention and missing data analysis, which are equally important in handling of missing data. Missing data prevention can be achieved through the enforcement of GSP and GCP during clinical trial process including clinical operations personnel training for data collection. It should be noted that despite the effort, missing data cannot be totally avoided, which may occur due to factors beyond the control of patients, investigators, and clinical project team.

FLEXIBILITY AND FEASIBILITY OF TWO-STAGE ADAPTIVE DESIGN

A seamless trial design is a study design that can address study objectives within a single trial that are normally achieved through the conduct of separate independent trials. A seamless adaptive design is a seamless trial design that fully utilizes data collected from patients before and after the adaptation in the final analysis. A seamless trial design is called a two-stage seamless design if it combines two studies into a single study. Thus, a two-stage (seamless) adaptive design consists of two phases (stages; each stage contains one study), namely, learning or exploratory phase and confirmatory phase. It reduces the lead time between studies (i.e., the first study and the second study). Most importantly, data collected at the learning phase are combined with those obtained at the confirmatory phase for final analysis.

For a two-stage adaptive design, since it combines two independent trials into a single study, the study objectives

Table 6 Classifications of two-stage adaptive designs

Study objectives	Study endpoint	
	S	D
S	SS	SD
D	DS	DD

S = Same; D = different.

and study endpoints at different stages (studies) could be different. Depending upon study objectives and endpoints used, two-stage adaptive trial designs can be classified into four categories of designs as indicated in Table 6.

Thus, we have SS, SD, DS, and DD designs, where SS designs indicate study designs with same objectives and same endpoints at different stages and so on. In clinical trials, different study objectives could be dose finding or treatment selection at the first stage and efficacy confirmation at the second stage. Different study endpoints could include biomarkers, surrogate endpoints, and clinical endpoints with different (shorter) treatment durations at the first stage versus clinical endpoints at the second stage or the same clinical endpoints with different treatment durations.

SS designs are similar to typical group sequential designs with one planned interim analysis. Thus, standard methods for a typical group sequential design can be directly applied to the SS designs.

In this article, our emphasis will be placed on SD, DS, and DD designs. In practice, typical examples for SD, DS, and DD designs include a two-stage phase I/II adaptive design, which is often employed in early clinical development, and a two-stage phase II/III adaptive design, which is usually considered in the late phase of clinical development. For example, for the two-stage phase I/II adaptive design, the study objective at the first stage is for biomarker development and the study objective at the second stage is to establish early efficacy. For a two-stage phase II/III adaptive design, the study objective at the first stage could be for treatment selection, whereas the study objective at the second stage could be for efficacy confirmation.

One of the most debatable issues regarding the flexibility and feasibility of the use of two-stage adaptive design in the early phase and/or late phase of clinical development is the efficiency and effectiveness of the trial design compared to the traditional approach (i.e., conducting two separate trials). To address this issue, Table 7 provides a simple comparison in terms of significance level, power, lead time, and sample size required for achieving a desired power.

As it can be seen from the table, the traditional approach by conducting two separate trials does provide substantial evidence at 1/400 level of significance with a 64% power, whereas the two-stage adaptive design will achieve an 80% power at the 5% (1/20) level of significance. Besides, the use of two-stage adaptive design could reduce the lead time between studies and hence shorten the process of clinical development. In terms of the sample size required, the use of two-stage adaptive design may also reduce the sample

Table 7 Simple comparison

	Two separate trials	Two-stage adaptive design
Significance level	1/20 * 1/20	1/20
Power	0.8 * 0.8	0.8
Lead time	6 month–1 year	Reduced lead time
Sample size	$n = n_1 + n_2$	$m < n?$

Note: n_1 and n_2 are the sample sizes for the two separate trials and m is the sample size for the two-stage adaptive design.

size required for achieving the desired power depending upon the study objectives and the study endpoints used at different stages in the two-stage adaptive trial design. Note that sample size calculation and statistical analysis for SD, DS, and DD designs can be found in the work of Chow and Chang.^[2]

When applying a two-stage adaptive design in clinical trials, one of the most challenging and debatable questions often asked by the regulatory agency such as the FDA is concerned that the overall type I error rate may not be controlled at a prespecified level of significance when (1) O’Brien-Fleming type of boundaries such as Lan-DeMets boundary and (2) additional adaptations are applied.

CHALLENGE OF THE INDEPENDENCE OF DMC

In clinical trials, a DMC is usually established to monitor the validity and integrity of the intended clinical trial. The DMC is independent from the project team, which performs ongoing safety monitoring and/or interim analyses for efficacy. Typically, a DMC consists of experienced physicians and biostatisticians. A charter is necessarily developed not only to outline the activities and functions of the DMC, but also to describe the roles and responsibilities of DMC members.

One of the major concerns regarding an established DMC is the independence of the DMC. The DMC has the authority to perform a review of unblinded data though most DMCs prefer a blinded review of interim data. After the review of interim data, the DMC has the authority to stop the trial early due to safety, futility, and/or efficacy. In clinical trials, an independent DMC ensures the quality, validity, and integrity of the clinical trial. Some sponsors, however, will make every attempt to influence the function and activity of the DMC, which have challenged the independence of the DMC. The following is a summary of some observations that are commonly seen in DMCs across various therapeutic areas:

1. DMC members are selected and appointed by the sponsors.
2. DMC charter is usually developed by the sponsor. The charter is developed without consulting with the

DMC members. DMC members usually do not have the chance to review it until the organizational meeting. As result, the charter is usually approved in a hurry.

3. The trial may have begun to enroll patients prior to the DMC organizational meeting.
4. Those DMC members who have disagreements with the sponsor are replaced prior to the DMC meeting. To avoid selection bias, it is suggested that the reasons for replacing DMC members be documented.
5. DMC members and investigators are from the same organization with administrative reporting relationship.
6. There is no single voice from the DMC.
7. The sponsor issues protocol amendments or modifies randomization schedules without consulting with DMC members.
8. The project statistician and the unblinded (or DMC support) statistician are the same person.

Based on the above observations, it is doubtful that an independent DMC is really independent. In addition, the following two debatable issues have also been raised: First, should the DMC directly communicate with regulatory agencies for any wrong doing in the conduct of the intended clinical trial? Second, can the DMC perform well if a less well-understood adaptive design is used in the intended clinical trial?

CONCLUDING REMARKS

In this article, several commonly encountered statistical controversial issues in clinical research are discussed. In practice, many more debatable issues are still under tremendous discussion among regulatory agencies, academia, and the pharmaceutical industry. These debatable issues include the issue of placebo effect, the impact of baseline adjustment, the selection of non-inferiority margin in active control trials, the use of Bayesian methods in clinical research, the issues in bridging and/or multinational (multiregional) studies, and the potential misuse and abuse of adaptive trial designs (especially those less well-understood design as described in the FDA draft guidance on the adaptive trial design). Most recently, the scientific/statistical issues on the assessment of biosimilarity and interchangeability of biosimilar drug products have received much attention. These issues such as “how similar is considered highly similar?” and “A biosimilar product is expected to produce the same clinical result in *any* given patient.” are debatable from different perspectives of regulatory agencies, academia, and pharmaceutical/biotech industry.

As discussed above, debatable issues are likely encountered in clinical trials. Consequently, the accuracy and reliability of statistical inference on the treatment effect is a concern to the investigator. To address this issue, Shao

and Chow^[17] and Chow and Shao^[4,18] proposed the concept of reproducibility and generalizability of evaluation of the accuracy and reliability of the clinical trials. The reproducibility is defined as the probability of observing positive results (which have achieved statistical significance) of future clinical trials that are conducted under similar experimental conditions given the observed significant positive clinical results. Shao and Chow^[17] suggested considering the probability of reproducibility a monitoring tool for the performance of a test treatment under investigation for regulatory approval. The evaluation of reproducibility provides valuable information that protects patients from the unexpected risk of the test treatment. For example, for a given clinical trial with a relatively low probability of reproducibility, the observed significant positive clinical results may not be reproducible if the clinical shall be repeatedly conducted under similar experimental conditions. To ensure that there is a high reproducibility (say 95%), Chow and Shao^[4] indicated that the p -value for the observed positive results should be less than 0.001 (i.e., the study has to be highly significant).

Abstract

Interval-censored failure time data are a general type of failure time or time-to-event data, where the failure time of interest is known or observed only to lie in an interval instead of being observed exactly. A common area where interval-censored data often occur is in medical or public health studies that entail periodic follow-ups such as clinical trials. In this situation, an individual due for the scheduled observations for a clinically observable change in disease status may miss some observations and return with a changed status, thus contributing to an interval-censored time of the occurrence of the change. This entry will overview and discuss some commonly used models and methods for the analysis of interval-censored failure time data as well as some advances in the area.

Keywords: Comparison of survival functions; Interval censoring; Non-parametric estimation; Semiparametric regression; Survival analysis.

INTRODUCTION

Interval-censored failure time or time-to-event data arise in many areas especially in cancer oncology and biopharmaceutics. Their analysis has attracted a great deal of attention. For example, two books have been published on this topic^[1,2] and also several review papers have been published including the study by Ma et al.^[3] and Sun and Li.^[4] In the context of failure time data, interval censoring means that the failure time variable of interest is observed or known only to lie within some intervals or windows instead of being observed exactly.^[1,5] If the observed interval includes only or reduces to a single time point, one obtains the exact failure time.

One field that often produces interval-censored failure time data is medical or public health studies that entail periodic follow-ups such as clinical trials. In these studies, an individual due for the prescheduled observations for a clinically observable change in disease or health status may miss some observations and return with a changed status. As a consequence, we only know that the true event time is greater than the last observation time at which the change has not occurred and less than or equal to the first observation time at which the change has been observed to occur. That is, we only have an interval that contains the real (but unobserved) time of

occurrence of the change. A representative and well-known example of interval-censored data is given by Finkelstein^[6] on comparing Radiotherapy Only treatment with Radiation + Chemotherapy treatment. The study consists of 94 patients with early breast cancer and they were supposed to be monitored every 4–6 months. Among them, 46 received radiation only and 48 received radiation plus chemotherapy. For the study, the event of interest is the time to the first appearance of moderate or severe breast retraction for which only interval-censored data are available. More discussion on this example will be given below. Another field that often produces similar data is the acquired immune deficiency syndrome (AIDS) trials. In this case, one maybe interested in times to AIDS for human immunodeficiency virus (HIV) infected subjects. The determination of AIDS onset is usually based on blood testing which can be performed only periodically but not continuously. In consequence, only interval-censored data are available for AIDS diagnosis times. A similar case is for studies on HIV infection times. If a patient is HIV positive at the beginning of a study, then the HIV infection time is usually determined by a retrospective analysis of his or her medical history. Therefore, we are only able to obtain an interval given by the last HIV negative test date and the first HIV positive test date for the HIV infection time.

In reality, interval censoring can occur in different forms, giving different types of interval-censored failure time data. Among them, an important type is the so-called current status data,^[1] which mean that each subject is observed only once for the occurrence of the failure event of interest. In other words, one does not directly observe the occurrence of the failure event but instead only knows the observation time and whether or not the event has occurred at the time. In consequence, the failure time is either left or right censored. One type of study that usually produce current status data is cross-sectional study on failure events and another type is tumorigenicity study in which the time to tumor onset is usually of interest but not directly observable. In these cases, one only knows or observes the exact value of the observation time, which is usually the death or sacrifice time of the subject. Note that for the first example, current status data occur due to the study design, while for the second case, they are often observed because of the inability of measuring the failure time variable directly and exactly. Sometimes we also refer to current status data as case I interval-censored data and the general case as case II interval-censored data.

Another type of interval-censored data is the so-called doubly censored data,^[7] which mean that the failure time of interest is defined as or represents the time between two related events and the observed data on the times to the occurrences of both events are interval censored. In contrast, the interval-censored data discussed above can be regarded as a special case of such doubly censored data in which one observes the times to the first event exactly and thus can treat them being zero for simplicity. An example of doubly censored data is provided by the AIDS studies discussed above where the variable of interest is AIDS incubation time,^[1] the time from HIV infection to AIDS diagnosis, with both HIV infection time and AIDS diagnosis time being right- or interval-censored.

This entry will discuss some commonly used models and methods for the analysis of interval-censored failure time data as well as some advances in the area. More specifically, after introducing some notation and assumptions, we will first discuss in some detail the analyses of univariate and multivariate interval-censored data, and then briefly review the analyses of some other types of interval-censored data. We will further introduce the available software for the analysis of interval-censored data and some final remarks will be given at last. We remark that this entry is a modified and updated version of Ma et al.^[3]

NOTATION, ASSUMPTIONS, AND LIKELIHOOD FUNCTION

We will first define some notation and describe the likelihood function along with some assumptions. Let T denote the failure time of interest. By saying that T is interval censored, we mean that the only available information for T is

an interval denoted by $I = (L, R]$ such that $T \in I$. Using the notation, we see that current status data correspond to the situation where either $L = 0$ or $R = \infty$. Interval-censored data reduce to right-censored data if $L = R$ or $R = \infty$ for all subjects in the study. Note that a more general way to describe interval-censored data is to assume that the observation on T is given by a group of intervals. However, we will not discuss this general representation as the resulting likelihood functions in both cases have essentially the same structure.

Suppose that there is a failure time study consisting of n independent subjects and let T_i and $I_i = (L_i, R_i]$ be defined as above but associated with subject i . Define $F(t) = P(T \leq t)$, the cumulative distribution function of T , and $S(t) = 1 - F(t)$, the survival function of T . Let $0 = t_0 < t_1 < \dots < t_m = t_{m+1} = \infty$ denote the unique ordered elements of $\{0, \{L_i\}_{i=1}^n, \{R_i\}_{i=1}^n, \infty\}$ and α_{ij} the indicator of the events $(t_{j-1}, t_j] \subseteq I_i$ and $p_j = S(t_{j-1}) - S(t_j)$. Then, for inference about S or about $p = (p_1, \dots, p_{m+1})'$, the likelihood function that is commonly used has the form:

$$L_s(p) = \prod_{i=1}^n [S(L_i) - S(R_i)] = \prod_{i=1}^n \sum_{j=1}^{m+1} \alpha_{ij} p_j \quad (1)$$

In reality, there may exist some covariates denoted by Z and in this case, the likelihood function above becomes:

$$L_s(p|Z_i's) = \prod_{i=1}^n [S(L_i|Z_i) - S(R_i|Z_i)] = \prod_{i=1}^n \sum_{j=1}^{m+1} \alpha_{ij} p_j(Z_i) \quad (2)$$

Of course, the likelihood functions given above come with some assumptions. The most fundamental and important one is perhaps the so-called non-informative interval censoring, which can be described by the following equality:^[1]

$$P(T \leq t | L = l, R = r, L < T \leq R) = P(T \leq t | l < T \leq r) \quad (3)$$

The assumption above essentially says that, except for the fact that T lies between l and r which are the realizations of L and R , the interval $(L, R]$ (or equivalently its endpoints L and R) does not provide any extra information for T . In other words, the probabilistic behavior of T remains the same except that the original sample space $T \geq 0$ is now reduced to $l = L < T \leq R = r$. In the presence of covariates, the assumption (3) becomes:

$$\begin{aligned} P(T \leq t | L = l, R = r, L < T \leq R, Z = z) \\ = P(T \leq t | l < T \leq r, Z = z) \end{aligned} \quad (4)$$

One could also employ different ways to characterize the non-informative interval censoring assumption. For example, one can use a stochastic process to describe the

underlying interval censoring mechanism by assuming that there exists a sequence of observation times or an observation process. Then, the non-informative assumption means that the process is independent of the failure time or process of interest.^[8] In practice, one question of interest is the conditions under which the assumption (3) or (4) holds and for this, the readers are referred to the discussion given in Oller, Gómez, and Calle^[9] among others. In the following, sections all discussion will be based on the assumption (3) or (4) unless specified otherwise.

STATISTICAL ANALYSIS OF UNIVARIATE INTERVAL-CENSORED DATA

In this section, we will consider statistical analysis of univariate interval-censored failure time data and mainly discuss three basic topics—non-parametric estimation of a survival function, non-parametric comparison of survival functions, and regression analysis with the focus on some of the new advances. In addition, some discussion about their applications will be provided.

For non-parametric estimation, one can easily see that given interval-censored data, the problem of finding the non-parametric maximum likelihood estimator (NPMLE) of the survival function S is equivalent to that of maximizing $L_s(p)$ given in Eq. (1) under the constraint that $\sum_{j=1}^{m+1} p_j = 1$ and $p_j \geq 0, j = 1, \dots, m+1$. Obviously, the likelihood function L_s depends on S only through the values $\{S(t_j)\}_{j=1}^m$. Thus, the NPMLE $\hat{S}$ of S can be uniquely determined only over the observed intervals $(t_{j-1}, t_j]$ and the behavior of S within these intervals will be unknown. Several methods have been proposed for maximizing $L_s(p)$ with respect to p . The first and simplest one is perhaps the self-consistency algorithm given by Turnbull.^[10] One drawback of the algorithm is that the convergence can be slow. To address this, Groeneboom and Wellner^[8] developed an iterative convex minorant (ICM) algorithm, which can be seen as an optimized version of the well-known pool-adjacent-violator algorithm for isotonic regression. Another faster algorithm is the EM iterative convex minorant (EMICM) algorithm, a hybrid one that combines the two approaches together. One can find some other procedures such as Bayesian methods and advances on this in the study by Ma et al.^[13]

It is worth to emphasize that all algorithms mentioned above are iterative and for general interval-censored data, the NPMLE $\hat{S}$ of S has no closed form, although for the special case, current status data, a closed form of $\hat{S}$ can be derived using max-min formula for the isotonic regression.^[11] Also, it should be noted that for general interval-censored data, the NPMLE may not be unique and the solutions derived from the algorithms mentioned above may not be the NPMLE. One sufficient condition for the uniqueness of the NPMLE is that the log likelihood is strictly concave. Another important but difficult issue with the NPMLE of S is the consistent variance estimation as

the standard Fisher information matrix approach does not work here. For this, one way is to employ the profile likelihood approach, which is often computationally intensive, and another method is the least-squares approach based on the efficient score function. For detailed discussion on these issues and the asymptotic properties as well as the differences between right-censored and interval-censored data, the readers are referred to the studies by Groeneboom and Wellner^[8] and Zhang and Sun,^[11] among others.

The comparison of different treatments or survival functions is another primary objective in most medical or clinical studies. To formalize the problem, suppose that there are K treatment arms in a clinical study and let $S^{(k)}(t)$ denote the survival function of the k^{th} arm with $k = 1, \dots, K$. Then the problem becomes testing the null hypothesis:

$$H_0: S^{(1)}(t) = S^{(2)}(t) = \dots = S^{(K)}(t) \text{ for all } t \quad (5)$$

In the case of right-censored data, many non-parametric test procedures have been developed and most of them can be classified into two categories—rank-based tests and survival-based tests. The fundamental difference between them is that the former relies on the differences between the estimated hazard functions, while the latter bases the comparison on the differences between the estimated survival functions. Among them, the log-rank test is perhaps the most widely used method and a few of them have been generalized to the case of interval-censored data.^[11] To give a representative of such procedures, in the following, we describe the one proposed by Zhao et al.^[12]

Consider a survival study consisting of n independent subjects with n_k subjects from treatment arm $k, k = 1, \dots, K$. Let the T_i 's and I_i 's be defined as before and D_{k1} and D_{k2} denote the sets of indices of the subjects in treatment arm k whose failure times are observed exactly and interval censored, respectively. Define $n_{k1} = |D_{k1}|$, $n_{k2} = |D_{k2}|$, $N_1 = \sum_{k=1}^K n_{k1}$, and $N_2 = \sum_{k=1}^K n_{k2}$, and let $\hat{S}$ denotes the NPMLE of the common survival function under the hypothesis H_0 . To test the hypothesis H_0 , Zhao et al.^[12] proposed to use the test statistic $U_\xi = (U_\xi^{(1)}, \dots, U_\xi^{(K)})'$, where:

$$U_\xi^{(k)} = \frac{N_1}{n_{k1}} \sum_{i \in D_{k1}} \frac{\xi(\hat{S}(T_i -)) - \xi(\hat{S}(T_i))}{\hat{S}(T_i -) - \hat{S}(T_i)} - \frac{N_2}{n_{k2}} \sum_{i \in D_{k2}} \frac{\xi(\hat{S}(L_i)) - \xi(\hat{S}(R_i))}{\hat{S}(L_i) - \hat{S}(R_i)} \quad (6)$$

and ξ is a positive known function over $(0,1)$. In practice, different ξ can be used and will yield different test statistics. The statistics above were motivated by that given in Peto and Peto,^[13] who discussed similar test statistics with $\xi(x) = x \log(x)$ for right-censored data. If $n_1 = 0$, that is, only interval-censored failure time data are available, the statistics U_ξ reduces to that proposed in the study by Sun, Zhao, and Zhao,^[14] a generalization of the log-rank

test discussed in the study by Peto and Peto.^[13] Under some regularity conditions and H_0 , Zhao et al.^[12] showed that as $n \rightarrow \infty$, $n_{k1}/n \rightarrow p_{k1}$, $n_{k2}/n \rightarrow p_{k2}$ with $0 < p_{kj} < 1$, $U_\xi/\sqrt{n}$ has an asymptotic normal distribution with mean zero. They also gave a consistent estimate of the asymptotic covariance matrix. Several other generalizations of both rank-based and survival-based non-parametric test procedures for right-censored data are available and can be found in Ma et al.^[3] and others.

One needs to perform regression analysis if there exist covariates and one is interested in, for example, quantifying the effect of covariates on the failure time of interest or predicting survival probabilities for new individuals. For this, the first step is usually to specify an appropriate regression model. For failure time data, the most commonly used model is perhaps the proportional hazards model.

$$\lambda(t|Z=z) = \lambda_0(t)e^{\beta'z} \quad (7)$$

with respect to the hazard function of T given covariates $Z = z$. Here $\lambda_0(t)$ denotes an unknown baseline hazard function and β the vector of unknown regression parameters. To fit model (7) to interval-censored data, in addition to the procedures discussed in Sun^[1] and Ma et al.,^[3] Wang et al.^[15] gave a spline-based maximum likelihood approach, where monotone B-splines were used to approximate the baseline cumulative hazard function. Another attractive semiparametric regression model often used in practice is the additive hazards model.

$$\lambda(t|Z=z) = \lambda_0(t) + \beta'z \quad (8)$$

again with respect to the hazard function of T given $Z = z$. It specifies that the effects of covariates are additive rather than multiplicative as in model (7). To fit model (8) to interval-censored data, some multiple imputation-based and estimating equation-based approaches have been developed.^[1,3]

In addition to the models (7) and (8), many other semiparametric models have been employed for regression analysis of interval-censored data. One such model is the proportional odds model expressed as:

$$\log\left(\frac{F(t|z)}{1-F(t|z)}\right) = h(t) + \beta'z \quad (9)$$

with respect to the conditional CDF $F(t|z)$ of the failure time T of interest given $Z = z$. Here, $h(t)$ is an unknown monotone-increasing function, also referred to as the baseline log odds, and β represents a vector of regression parameters as in models (7) and (8). The accelerated failure time model has also been considered for analyzing interval-censored data and it assumes that T and Z have the following relationship:

$$\log(T) = \beta'Z + \varepsilon \quad (10)$$

In the above, β is defined as before and ε is an error term whose distribution is usually unspecified.

It is easy to see that the four semiparametric models (7) to (10) are all specific models in terms of the functional form of the effects of covariates. Sometimes, one may prefer a model that gives more flexibility. One such model that has been investigated for interval-censored data is the linear transformation model that specifies the relationship between the failure time T and the covariate Z as:

$$h(T) = \beta'Z + \varepsilon \quad (11)$$

Here, $h: \mathbb{R}^+ \rightarrow \mathbb{R}$ ($\mathbb{R}$ denotes the real line and $\mathbb{R}^+$ the positive half real line) is an unknown strictly increasing function and the distribution of ε is assumed to be known. It is apparent that the model above gives different models depending on the specification of the distribution of ε and, especially, it includes models (7) and (9) as special cases. For inference about the model based on interval-censored data, some multiple imputation-based and empirical likelihood-based methods have been developed.^[3]

For a practical problem, one may also employ some parametric models such as piecewise exponential models,^[11] if there exists some prior information about the appropriateness of the model. A main advantage of adopting a parametric model is that one can readily apply the maximum likelihood approach for inference. On the other hand, it is well-known that parametric models usually may be too difficult to be verified and are less flexible than semiparametric models.

Besides the issues and models discussed above, some other issues or models regarding regression analysis of interval-censored data have been investigated. One such issue is to fit a cure model to interval-censored data in which it is assumed that there exists a cured subgroup. Another is to analyze interval-censored data with time-dependent covariates or using regression models with time-varying coefficients. Other regression models that have been considered in the literature but not mentioned above include the probit model, Cox-Aalen model, and non-proportional hazards models; and in particular, Zeng, Mao, and Lin^[16] studied a class of semiparametric transformation models that can accommodate time-dependent covariates. Some Bayesian approaches are also available for regression analysis of interval-censored data. Ma et al.^[3] gave more detailed discussions and references on these.

To give an illustration of the methods discussed above, we will briefly discuss the breast cancer study mentioned before. Recall that the objective of the study is to compare Radiotherapy Only treatment (46 patients) to Radiation + Chemotherapy treatment (48 patients) with respect to the time to the first appearance of moderate or severe breast retraction. For the problem, by applying the score test in Finkelstein,^[6] we can obtain a p value of 0.004 for comparing the two groups. If using the generalized log-rank test in Sun et al.,^[14] the p value would be 0.007. Both

methods suggested that adding chemotherapy to radiotherapy significantly increased the hazard of breast retraction.

STATISTICAL ANALYSIS OF MULTIVARIATE INTERVAL-CENSORED DATA

Multivariate interval-censored data arise if a failure time study involves several related failure time variables of interest and each of them suffers interval censoring. It is apparent that the analysis would be straightforward if the variables are independent, and when they are not independent of each other, as is usually the case, one needs to and should employ the inference procedures that can take into account the correlation among the failure time variables. Another difference between univariate and multivariate interval-censored data is that for the latter, a new and unique issue that does not exist for the former is to make inference about the association between the failure time variables. In the following, we will first discuss a couple of basic issues related to the analysis of multivariate interval-censored data and then some advances, with the focus on bivariate interval-censored data.

As with univariate interval-censored data, non-parametric estimation of a survival function is also one of the primary objectives in practice for multivariate interval-censored data. To discuss this, consider a survival study that involves n independent subjects from a homogeneous population with each subject giving rise to two failure times denoted by T_{1i} and T_{2i} , $i = 1, \dots, n$. Let $F(t_1, t_2) = P(T_{1i} \leq t_1, T_{2i} \leq t_2)$ denote their joint cumulative distribution function and suppose that only interval-censored failure time data in the form $\{U_i = (L_{1i}, R_{1i}] \times (L_{2i}, R_{2i}]\}$, $i = 1, \dots, n$ are available, where $(L_{1i}, R_{1i}]$ and $(L_{2i}, R_{2i}]$ represent the intervals to which T_{1i} and T_{2i} belong, respectively. It is easy to see that the observation on each subject could be a point, line segment, or a rectangle. If one treats points as rectangles that degenerate in both dimensions and line segments as rectangles that degenerate in one dimension, then the observed data consist of a collection of n rectangles.

For the determination of the NPMLE of F , note that as with univariate data, it will be a step function. Let $H = \{H_j = (r_{1j}, s_{1j}] \times (r_{2j}, s_{2j}]\}$, $j = 1, \dots, m$ denote the disjoint rectangles that constitute the regions of possible support of the NPMLE of F and define $\alpha_{ij} = I(H_j \cap (L_{1i}, R_{1i}] \times (L_{2i}, R_{2i}])$ and $p_j = F(H_j) = F(s_{1j}, s_{2j}) - F(r_{1j}, s_{2j}) - F(s_{1j}, r_{2j}) + F(r_{1j}, r_{2j})$, $i = 1, \dots, n$; $j = 1, \dots, m$. Then, the likelihood function has the form:

$$L_s(p) = \prod_{i=1}^n F(U_i) = \prod_{i=1}^n \sum_{j=1}^m \alpha_{ij} p_j \quad (12)$$

Again assuming non-informative interval censoring with $p = (p_1, \dots, p_m)'$, and the NPMLE of F can be determined by maximizing Eq. 12 over the p_j 's subject to $p_j \geq 0$ and $\sum_{j=1}^m p_j = 1$. One can easily see that the likelihood functions given Eqs. 1 and 12 actually have the same structure and

thus the algorithms developed for the maximization of Eq. 1 could be employed here for the maximization of Eq. 12 assuming that H is known. However, for a given data set, the determination of H is actually not straightforward, and for this, some algorithms have been developed and can be found in the study by Sun.^[1] It is apparent that the same holds for general multivariate interval-censored data.

As mentioned above, the estimation of the association between related failure time variables is often of interest for multivariate failure time data. To discuss this in the context of bivariate data, let $S_1(t)$ and $S_2(t)$ denote the marginal survival functions of possibly related T_1 and T_2 , respectively, and $S(t_1, t_2) = P(T_1 > t_1, T_2 > t_2)$ their joint survival function. For the problem, one common way is to assume that $S(t_1, t_2)$ can be expressed by a copula model as $S(t_1, t_2) = C_\alpha(S_1(t_1), S_2(t_2))$, where C_α is a distribution function on the unit square and $\alpha \in \mathbb{R}$ is a global association parameter. One attractive feature of the above expression is its flexibility as it includes as special cases many useful bivariate failure time models such as the Archimedean copula family. Another attractive feature is that under this expression, the marginal distributions do not depend on the choice of the association structure and thus one can model the marginal distributions and the association separately.^[1,3] Of course, by using high-order copula models instead of the bivariate model, one can apply the same approach to general multivariate interval-censored data.

For regression analysis of multivariate interval-censored data, one can apply the same copula model approach as described above; and, for example, some efficient estimation procedures have been developed in the literature for the fitting of models (7) and (9) to bivariate current status data.^[3] Besides the copula model approach, another commonly used approach is to employ frailty or latent variable approaches in which some latent variables are used to characterize the correlation.^[1,3] Among others, one development was given by Zhou, Hu, and Sun,^[17] who considered regression analysis of general bivariate interval-censored data and presented an efficient sieve estimation procedure. A third approach that is often adopted for multivariate failure time data is the marginal model approach that leaves the correlation arbitrary, and several such estimation procedures can be found in the literature for inference about models (8), (9), and (11) based on general multivariate interval-censored data.^[3,4] For all three approaches, of course, one could put them in the Bayesian framework and find some existing work in the literature too.^[1]

It is well-known that multivariate failure time data can be seen as a special case of clustered failure time data and a key feature of the latter is that the cluster size, the number of correlated failure time variables, can differ from cluster to cluster. Thus, the existing methods for multivariate interval-censored data cannot be directly applied to clustered interval-censored data. Ma et al.^[3] described some

literature on the latter, and in particular, some inference procedures have been developed for the analysis under the proportional hazards model (7) with or without a cured subgroup. Also, Chen, Sun, and Xiong^[18] gave a multiple imputation-based estimation procedure under the additive hazards model. Compared to other types of interval-censored data discussed above, however, there exists very limited literature on clustered interval-censored data.

STATISTICAL ANALYSIS OF OTHER INTERVAL-CENSORED DATA

In this section, we will briefly discuss a few other types of interval-censored data that may occur in failure time studies, including competing risks interval-censored data, informatively interval-censored data, and doubly censored data.

Competing risks failure time data arise when there exist several related failure causes or types.^[5] The underlying structure behind them is actually similar to that behind multivariate failure time data. A key difference between the two types of data, also a key feature of the former, is that one observes only one failure type or one of several related underlying failure time variables. For a patient with several diseases, for example, one can observe the death time caused by one disease but not the times due to other diseases. Some work and references on interval-censored competing risk data can be found in Ma et al.,^[3] but as with clustered interval-censored data, there exists only limited literature on the topic.

In the previous sections, it has been assumed that the mechanism behind interval censoring is independent of the underlying failure time or process. In some applications, however, this assumption may not hold. For example, in medical or health follow-up studies, the patients with more serious conditions or diseases tend to see doctors more frequently. The situation where the censoring mechanism is related to the failure time is usually referred to as informative or dependent censoring.^[1] In addition to the literature described in Ma et al.,^[3] some more references on the topic include Ma, Hu, and Sun,^[19,20] who discussed the inference about the proportional hazards model, and Zhao et al.,^[21,22] who investigated the same estimation procedure but under the additive hazards model. Also Wang, Zhao, and Sun^[23] considered the situation where a sequence of observation times for each subject is available and the failure time of interest follows model (7).

As mentioned above, the interval-censored data discussed above can be regarded as a special case of doubly censored data, where the failure time of interest represents the elapsed time between two related events and the observations on both events suffer interval censoring. For the detailed discussion and general development on this type of failure time data, readers are referred to the study by Sun,^[1] who devoted one chapter for the topic, and the

study by Ma et al.,^[3] who also provided some discussion and literature. Furthermore, Wang et al.^[24,25] considered the situation where in addition to interval censoring, there may also exist left truncation and provided some inference procedures for the additive hazards model.

SOFTWARE FOR THE ANALYSIS OF INTERVAL-CENSORED DATA

It is well-known that software development is important for both the implementation of the developed methods and practitioners. Although there is no commercially available statistical software that is specifically designed for an extensive coverage of or covering most of the existing inference procedures for interval-censored data, there exist some packages or functions in R, SAS, or SPLUS that can be applied to the analysis of interval-censored failure time data.

In R, for example, the packages *interval* and *Icens* can be used to find the NPMLE of the survival and distribution function, and *interval* can also be used to perform two-sample weighted log-rank tests and k-sample tests. In addition, parametric methods are provided in the *survival* package using the *survreg* function and for semiparametric estimation, one can use *Icens* function in the *Epi* package. The *intcox* package can also be used for semiparametric estimation under the proportional hazards model. However, this package does not directly provide standard error estimation for the estimated regression parameters and the bootstrapping approach is one of the remedies for this drawback. Furthermore, the package *glrt* provides functions to perform four generalized log-rank tests including those given in the studies by Sun, Zhao, and Zhao^[14] and Zhao et al.^[12] as well as Finkelstein's score test. In addition, the packages *ICBayes*, *ICsurv*, *coxinterval*, and *dynsurv* were developed for semiparametric analysis of interval-censored data. *ICBayes* fits several Bayesian semiparametric regression models,^[26] *ICsurv* implements the expectation and maximization (EM) algorithm developed by Wang et al.^[15] for finding the maximum likelihood estimation (MLE) under the proportional hazards model, *coxinterval* provides the fit to the Cox-Aalen model,^[27] and *dynsurv* includes functions to fit Bayesian Cox model with time-independent, time-varying, or dynamic coefficients. One can find some details and examples on the use of R for the analysis of interval-censored data in the studies by Fay and Shaw^[28] and Gómez et al.,^[29] among others. In SPLUS, the function *kaplanMeier* can be used to compute the Turnbull estimator.

In SAS, the analysis of interval-censored data can be performed by, among others, the *LIFEREG* and *RELIABILITY* procedures, and the macros *%EMICM*, *%ICSTEST*, *%ICE*, *%INTCEN_\$SURV_P*, and *%TURNBULL_INT*. Some descriptions of them can be found in SAS website or in the study by Ma et al.^[3] the *ICLIFETEST* procedure

was specifically developed for analyzing interval-censored data and it offers a set of non-parametric statistical methods (e.g., EMICM, Turnbull's algorithm, and ICM) of estimating survival functions and statistical tests (e.g., weighted generalized log-rank tests with a variety of weight functions) for comparing survival functions of different groups. The methods used by the macros %EMICM, %ICSTEST, and %ICE have been incorporated into the ICLIFETEST procedure with minor modifications. Another SAS procedure is the ICPHREG procedure that can be used to fit the proportional hazards models with a variety of configurations in terms of the baseline hazard function (e.g., the piecewise constant model and the cubic spline model) by MLE based on the full likelihood.

CONCLUSION

This entry provided a relatively comprehensive overview of the issues and approaches in the analysis of interval-censored failure time data. It is apparent that given the page limit, there exist many issues that have been investigated but not discussed fully or not discussed at all, in the previous sections. These include the analysis of interval-censored data with missing covariates and/or truncation and the analysis of mixed interval-censored data. For more complete references, the readers are referred to the book by Sun^[1] and the reviews by Ma et al.^[3] and Sun.^[7] In addition, methodologically, there are many open questions in this area. Examples include but are not limited to model checking techniques and joint modeling of longitudinal and interval-censored data. Some of the methods discussed in the previous sections also need proper theoretical justifications. A major difficulty is the lack of basic tools as simple and elegant as the partial likelihood and the martingale theory for right-censored data. One can find some comprehensive theoretical work in the studies by Groeneboom and Wellner^[8] and Huang and Wellner,^[30] which mainly rely on complicated empirical processes and the optimization theory and are difficult to generalize.

Clinical Trials: Investigating Quality-of-Life

Patricia B. Cerrito

University of Louisville, Louisville, Kentucky, U.S.A.

Abstract

Medications that are potent enough to treat cancer can cause many serious adverse effects. This entry investigates the question of at what point is the toxicity of a treatment the cause of more suffering than life without it. This question is addressed by surveying patients about their quality of life while undergoing continuous treatment.

INTRODUCTION

In many cases, treatment for cancer cannot cure the disease but can only prolong life. However, treatment comes at a cost. Medications that are potent enough to treat cancer can cause many serious adverse effects. At what point is the toxicity of a drug sufficiently high enough to cause greater suffering than prolonged life? What is the risk of the toxic effect compared to the corresponding drug benefit?

To answer these questions, quality of life needs to be examined along with treatment effects in all drug studies. Because the assessment of the quality of life is subjective, patients need to be routinely consulted about their perception of treatment benefits. Measuring the patient's perception of the benefits of treatment will require the use of quality-of-life (QOL) surveys, either those that have been developed previously or one uniquely designed for a particular drug study. In this paper, the use of both types of surveys are discussed. Also, the use of QOL information to adjust patient outcomes is discussed.

EXISTING QUALITY-OF-LIFE INSTRUMENTS

One generalized QOL instrument, SF-36, was developed by the Rand Corporation.^[1,2] This instrument was designed to be relatively generic and relatively simple to administer and score. The SF-36 contains a total of 36 questions, and the Rand Corporation provides general permission for investigators to use the instrument and posts the scoring instructions on its website. The European Organization for Research and Treatment of Cancer (EORTC) has developed a QOL instrument targeted more specifically for cancer patients and containing modifications for different types of cancer. The instrument consists of 30 items divided among five functional subscales (physical, role, cognitive, emotional, and social), three symptom subscales (fatigue, pain, and nausea), as well as global health and quality

scales.^[3,4] Other instruments exist, but these two are the ones primarily used. The question of whether to use generic instruments, such as the SF-36, or specific instruments, such as the EORTC questionnaire, remains open.^[4–7] The advantage of using more generic instruments is that tests have been conducted to demonstrate their validity.^[8–10]

DEVELOPING QUALITY-OF-LIFE INSTRUMENTS

A specific QOL instrument can be developed for a specific clinical trial, one that is closely tailored to the aims and outcomes of the trial. However, care must be taken to ensure the validity of the instrument. The first step in the developmental process is to decide what important characteristics need to be measured. It is also important to determine any constraints. The major requirements of a QOL instrument are reliability, validity, and responsiveness. Generally, reliability is defined as freedom from measurement error. Validity is defined as the extent to which the survey measures what it is supposed to measure. Responsiveness is the extent to which the survey measures change over time.^[3] There are also some practical issues, including ease of use. For example, compliance with completing a QOL form decreases with the length of the form. Moreover, any instrument should focus on three different domains: physical, psychological (mental, emotional), and social. A brief outline is given in Suhonen et al. (Table 1).^[11]

Content validity suggests that the items in the instrument are meaningful to the quality of life to be studied. The language in the instrument must be clear, precise, and should result in clear subject responses. If there is any garbled language, it must be changed before the instrument is used. The instrument has construct validity if the questions represent specific topics that should be included. For example, suppose that there are 25 questions in the instrument. The questions should relate to several subtopics such as

Table 1 Development of Quality-of-Life Instrument

Purpose	Method
Examine concepts	Literature review
Develop instrument questions	Construction of instrument
Assess content validity	Expert review
Assess clarity of items	Expert review
Test instrument	Pilot sample
Test reliability and validity	Statistical methods
Test stability of instrument	Test–retest
Assess construct validity	Principal component analysis

physical functioning, mental functioning, and social functioning. Before any statistical analysis, the investigator should have an idea as to which questions relate to which topic. A principal component analysis (or factor analysis) is a statistical method for grouping such responses to specific subtopics. The statistical grouping should match the investigator's expectations. Although construct validity is a complex issue, it can be somewhat routinely investigated.^[12–14] Reliability indicates that similar questions receive similar responses. An instrument can be reliable without being valid, and care must be taken to examine both issues.

For a recent cancer trial, the author of this article developed a QOL instrument. The principal investigator (PI) of the study wanted to restrict the form to one page because the coinvestigators did not want to use a form that was longer.

The form was primarily restricted to physical and emotional symptoms, asking the patients to note the presence or absence of such symptoms. The purpose of the instrument was to have patient input in the definition of utilities that are used in adjustments to survival analysis. The instrument was reviewed by all participating clinicians before its use in the study. The questions were based upon potential adverse effects from using the drug, as identified in previous studies. In particular, previous studies demonstrated the acute adverse effects of chills, malaise, and arthralgias, and chronic adverse effects of fatigue, anorexia, weight loss, and depression.^[15] The documented depression reached the clinical criteria for major depression in some patients.

Statistical analysis to demonstrate the validity of the instrument was performed on 1200 patients who had up to 3 years of follow-up, approximately halfway to completion of the study (Table 2). There are a number of values that are statistically significant between treatment and control groups. The percentages listed in Table 2 indicate the number in each category identifying a symptom. Note that with 1200 patients, almost all the factors are statistically significant. The data were split at the 12-month interval because treatment was given for 1 full year. Interestingly, a number of the symptoms persisted beyond the treatment period.

Patients were also asked to identify, on a scale of 1 to 10, their general quality of life and general physical condition. For the first 12 months, there was a slight difference between treatment and control (Figs. 1 and 2). There was also an improvement in the treatment group before and

Table 2 Examination of Quality-of-Life Factors

Symptom	0–12 months			Over 12 months		
	No drug	Drug	P-value	No drug	Drug	P-value
Weak	22 (17%)	55 (50%)	<0.0001	4 (6%)	8 (15%)	0.1417

Shortness of breath	9 (7%)	19 (17%)	0.0154	0 (0%)	7 (13%)	0.0035
Swelling	22 (17%)	16 (14%)	0.5611	1 (2%)	2 (4%)	0.4806
Loss of appetite	1 (1%)	31 (28%)	<0.0001	0 (0%)	1 (2%)	0.2825

Fig. 1 Quality of life changes before and after the 12-month mark for patients in treatment arm

Fig. 2 Physical condition before and after the 12-month mark for control arm

after the termination of treatment. A much higher proportion of satisfaction with QOL (29% vs. 7%) in the control group indicates the highest level of physical condition after treatment. A similar increase (36% vs. 13%) in answers occurred in the highest level of overall quality of life. The proportions remained relatively stationary for the control group. However, there was a difference in responses in the treatment group in the 12 months of treatment compared with the time period after treatment.

Similarly, drug treatment was shown to interfere with a patient's employment. Patients taking treatment reported greater absenteeism from work (Fig. 3). The patients found that the drug generally interfered with their daily routine (Fig. 4).

Factor analysis was performed to determine how the variables interacted with each other (Table 3). Note that the use of the drug is strongly related to physical variables such as weakness and fever but not as strongly related to mental variables. Similarly, time of follow-up is strongly

Fig. 3 Time absent from work at less than 12 months

Table 3 Factor Loadings of Quality-of-Life Variables

Factor variable	Loading
1	
Irritable	0.55
Depressed	0.6
Forgetful	0.5
Anxious	0.71
Confused	0.61
Hungry	0.44
Sad	0.72
Nervous	0.6
2	
Weak	0.45
Feverish	0.58
Constipation	0.6
Diarrhea	0.49
Loss of appetite	0.57
Drug group	0.57
3	
Percent of routine	0.41
Tired	0.52
Muscle pain	0.55

Follow up month	0.62
Absent from work	0.58
Unable to do routine	0.5

Fig. 4 Interfering with routine at less than 12 months

related to the percentage of time a patient is absent from work and unable to perform a normal routine.

Social status was examined, in part, through questions concerning life changes such as marriage, divorce, or retirement (Fig. 5).

There was actually a higher proportion of patients from the control group who applied for social security and Medicare than from the treatment group. However, the proportions were so small that none were statistically significant.

Fig. 5 Comparison of life factors

Q-TWIST ANALYSIS

The general Q-twist method is a quality-adjusted survival analysis that integrates quality of life considerations into treatment comparisons.^[16] The survival time is adjusted according to the quality of life experienced. The equation is defined by^[17]

$$\text{Q-twist} = (u_{\text{TOX} \times \text{TOX}}) + \text{TWiST} + (u_{\text{REL} \times \text{REL}})$$

where TOX is the time with treatment toxic side effects; TWiST is the time without symptoms of disease and toxic side effects; REL is the time following recurrence; u_{TOX} is utility, or value of TOX relative to TWiST; u_{REL} = utility, or value of REL relative to TWiST.

The average duration of TOX, TWiST, and REL must be estimated from clinical data. The value assigned depends on the level of toxicity. Often, the toxicity definitions used are defined only by physicians.^[15]

No input from patients is used to define patient utilities.^[18–20] It is preferable to design a measurement of quality of life prior to enrolling patients, rather than to determine the level of toxicity once the patient data have been collected.

The Q-twist analysis is a form of quality-adjusted life years (QALYs). In this type of analysis, decisions are made based upon preferences. For example, how many years of life (x) is a patient willing to give up to have some years in good health (y). The primary problem with QALYs analysis is that these preferences are usually examined as hypothetical questions, and it is questionable just how relevant the responses are to actual situations. Similarly, for the Q-Twist, the major problem is in defining the utilities u_{TOX} and u_{REL} . It is clear that even minor changes in TOX value can result in substantially different outcomes and decisions.^[3] Therefore care must be taken to validate the utility weights used in the equation. The weights are defined using the factor loadings in Table 3.

The current standard practice is to vary the value of the utility weight to determine where changes in outcomes can occur. For example, consider the survival difference between control and treatment (Fig. 6).

Consider the adjustments to the survival. Assume that the toxic effect is chronic and continues through the duration of the time on medication. Assume that the utility is equal to 0.5 when compared to the time off the drug. The adjusted survival curves are given in Fig. 7, along with additional measures of toxicity. Note that, although the end result is closer, the adjusted survival still indicates the benefit of treatment.

Fig. 6 Survival differences between control and treatment

Fig. 7 Survival differences between control and treatment using sensitivity analysis of Q-twist adjustments

CONCLUSION

Because of the toxicity of treatments for various forms of cancer, it is helpful to determine whether the treatment adds or detracts from the overall quality of life. It is possible to use preexisting questionnaires that measure QOL issues. However, it is also possible to develop a valid, reasonable tool that is specific to a clinical trial. Care must be taken to ensure that the tool satisfies construct validity. If possible, both a new and an established tool can be used simultaneously to demonstrate convergent validity.

Department of Biostatistics, Gillings School of Global Public Health, University of North

Carolina, Chapel Hill, North Carolina, U.S.A.; Department of Statistics, University of

Pretoria, Pretoria, South Africa

Abstract

Given the globalization of drug development, clinical trials for biopharmaceuticals are most often conducted as multicenter, multiregional trials. Meta-analysis presents an efficient, effective method for combining the statistical data from large, global clinical trials and for increasing the reliability of statistical findings and the conclusions based on those data. This entry presents an overview of meta-analysis and emphasizes the use of the classical fixed-effects and random-effects models to synthesize summary statistics from multiple studies. In addition, meta-regression is used to explain between-study heterogeneity. The meta-analysis models are illustrated using real meta-data collected in 13 clinical trials to assess the efficacy of Bacillus Calmette-Guerin vaccine to prevent tuberculosis; the meta-analyses are implemented in open source R software.

Keywords: DerSimonian-Laird estimator; Fixed-effects model; Heterogeneity; Meta-analysis; Meta-regression; Random-effects model; Weighted-mean estimator.

INTRODUCTION

The development and testing of new biopharmaceuticals has become globalized because many regulatory bodies in different countries require safety and efficacy data obtained from a local patient sample before approving a new drug. To meet these requirements, clinical trials for biopharmaceuticals are most often conducted as multicenter, multiregional trials that offer some distinct advantages over single-site trials. For example, multiregional clinical trials (MRCT) tend to have a larger total sample sizes and are typically conducted in multiple, targeted regions to meet regulatory requirements, and thus, speed-up approval and reduce the time lag in getting a product to market. Global MRCTs can cover multiple regions in one country or can include several countries (e.g., trials in Japan and the United States) or broad global regions (e.g., Europe, Asian-Pacific countries, South America, and Africa). However, ever-changing and differing data requirements across countries can mean biopharmaceutical developers have to institute additional animal or clinical studies that increase development costs and delays patients' access to new drugs. A call for harmonization of these regulatory standards has prompted the U.S. Food and Drug Administration (FDA), the European Medicines Agency (EMA), and the Japanese Pharmaceuticals and Medical Devices Agency (PMDA) to release guidelines regarding the synthesis and meta-analysis of data from MRCTs as a step

toward international harmonization of scientific standards and regulatory requirements. Despite some advances in the harmonization of MRCTs, many challenges remain related to the potential for regional and between-study heterogeneity. Researchers must give careful consideration to this heterogeneity, which stems from the differing regulatory requirements in different countries regarding study design and practices for conducting an MRCT. Specifically, heterogeneity is generated from: (1) differences in the endpoints required to meet regional regulatory requirements because regional authorities have differing standards for primary, co-primary, or key secondary endpoints; (2) different time points required for hypothesis testing because of across-regions inconsistencies in the expected treatment duration or the primary time point for measuring treatment response; (3) differences in experimental designs that result from modifications made to match the differing characteristics of the various regions in an MRCT; (4) differing margins of non-inferiority as determined by different regulatory agencies; and (5) different analytic patient populations as defined in the analysis plans designed for different regions. Any one of these differences could lead to inflated type-I and type-II errors from the perspective of statistical analysis. Thus, it is imperative to follow the guidelines promoting global harmonization that have been provided by health and regulatory authorities such as the International Conference on Harmonization (<http://www.ich.org>).

Among the various methods available for synthesizing data from MRCTs, meta-analysis is a statistical method that is increasingly popular and widely used for examining the validity of the effect-sizes from each component trial in an MRCT, for quantifying the heterogeneity between the effect-sizes, and for providing an estimate of the overall pooled effect-size with optimal precision. With the rising costs and time investment associated with developing MRCTs, many trials are carried out with relatively small samples of patients, resulting in underpowered studies that lack the statistical power to be useful in detecting clinical trial effect-size. As a result, this small trial phenomenon increases the likelihood that separate clinical trials in an MRCT will produce conflicting results. However, by using meta-analytic methods to pool the estimated effect-size from each constituent trial in an MRCT, the data from a larger number of patients can be used and the statistical power can be increased.

In the literature, the term meta-analysis is traditionally defined as a statistical procedure for systematically combining data from multiple studies to reach a single conclusion with greater statistical power than any of the component studies. Most often in the literature, the term is used to refer to the meta-analysis of summary statistics from published studies, or summary statistics meta-analysis (SS-MA). The purpose of a meta-analysis of MRCT is to combine the estimates of study effect-sizes using the well-established approaches of the fixed-effects and random-effects models, which differ fundamentally on whether between-study heterogeneity is incorporated. These traditional meta-analysis models have played an increasingly important role in biopharmaceutical, health, and medical sciences, and meta-analyses of clinical trial data have led to numerous scientific discoveries. For example, since 2000, *The New England Journal of Medicine* has published more than 500 articles that reported results from a meta-analysis. In addition, since 2000, an increasing number of books have been published on SS-MA methods and applications.^[1–5]

This entry is organized to present an overview of methods and then an illustration of the methods. Section “Overview of meta-analysis” gives an extensive overview of meta-analysis using summary statistics. Specifically, the section presents a review of the classical SS-MA using; (1) fixed-effects and random-effects MA models; (2) an overview of quantification of heterogeneity with Q-statistic, τ^2 index, H index, and I^2 index; and (3) a review of the use of meta-regression to explore the heterogeneity with study-level moderators. Section “Meta-analysis using R” then illustrates the meta-analysis using a real dataset obtained from 13 clinical trials conducted to assess the impact of a *Bacillus Calmette–Guerin* (BCG) vaccine in the prevention of tuberculosis (TB). Detailed analysis using open source R software is illustrated in this section so readers can follow the meta-analysis for their own data analysis. The entry ends with concluding remarks.

OVERVIEW OF META-ANALYSIS

Summary Statistics and the Sources of Variations

In a typical meta-analysis with summary statistics, K independent studies are obtained to estimate a parameter of interest, such as the effect-size of efficacy between a new treatment and a control, β_k ($k = 1, 2, \dots, K$). This analytic approach can be applied to a broad range of study designs, including single-arm or multiple-arm studies, randomized controlled trials, and observational studies. For ease of illustration, this discussion focuses on MA with two-arm studies, where β_k is some form of the effect-size between the two groups. The most popular choices for β_k for a continuous outcome are the mean difference or the standardized mean difference; for a dichotomous outcome, the most popular choices are odds ratio, risk ratio, and risk difference. In most cases, an estimated $\hat{\beta}_k$ of the true β_k and its associated standard error (SE) could be directly extracted from each study. The ultimate goal of meta-analysis is to produce an optimal estimate of the overall population effect-size by pooling the estimates $\hat{\beta}_k$ ($k = 1, 2, \dots, K$) from individual studies using appropriate statistical models.

Two sources of errors or variations exist in these summary statistics of $\hat{\beta}_k$ from different studies, with one source being the within-study variation and the other source being the between-study variation. Within-study variation is caused by sampling error, which is random or nonsystematic within each study. In contrast, between-study variation results from systematic differences among studies. If the between-study variation can be verified as being zero, the effect estimates $\hat{\beta}_k$ are considered homogeneous—otherwise, the effect estimates are heterogeneous. In MA, the assumption of homogeneity states that β_k ($k = 1, 2, \dots, K$) is the same in all studies, i.e.,

$$\beta_1 = \beta_2 = \dots = \beta_K = \beta. \quad (1)$$

If these studies are homogeneous, then two commonly used meta-analysis models can be used—the fixed-effects MA model and random-effects MA model.

Fixed-Effects Meta-Analysis

As shown in Eq. 1, a fixed-effects meta-analysis assumes homogeneity when the underlying population effect-sizes β_k are constant across all studies. A typical fixed-effects model is described as:

$$\hat{\beta}_k = \beta + \epsilon_k; k = 1, 2, \dots, K, \quad (2)$$

where $\hat{\beta}_k$ represents the effect-size for study K and β is the overall global population effect-size. The ϵ_k are the sampling error with mean 0 and KNOWN variance $\hat{\sigma}_{\beta_k}^2$ which can be extracted or calculated from the individual studies.

In general, the ε_k is assumed to follow a normal distribution $N(0, \hat{\sigma}_{\beta_k}^2)$. A pooled estimate of β in fixed-effects MA models is given by the weighted least square estimation,

$$\hat{\beta}_F = \frac{\sum_{k=1}^K w_k \hat{\beta}_k}{\sum_{k=1}^K w_k}, \quad (3)$$

and the variance of $\hat{\beta}_F$ can be expressed as:

$$\text{Var}(\hat{\beta}_F) = 1 / \sum_{k=1}^K w_k \quad (4)$$

where a popular choice of weight is $w_k = 1 / \hat{\sigma}_{\beta_k}^2$ and variance $\hat{\sigma}_{\beta_k}^2$ is estimated from study K. Hence, the 95% confidence interval of β_F is given by,

$$\hat{\beta}_F - z_{0.025} \sqrt{\text{Var}(\hat{\beta}_F)} \leq \beta \leq \hat{\beta}_F + z_{0.025} \sqrt{\text{Var}(\hat{\beta}_F)}, \quad (5)$$

where $z_{0.025}$ denotes the 2.5%-percentile of the standard normal distribution. Similarly, a statistical z-test can be formulated as:

$$z = \frac{\hat{\beta}_F - \beta}{\sqrt{\text{Var}(\hat{\beta}_F)}} \quad (6)$$

to be used to test $H_0: \beta = 0$.

Random-Effects Meta-Analysis

When meta-analyzing effect-sizes from a group of studies, it may be impractical to follow the assumption of the fixed-effects model that the K true effect-sizes are the same for all studies. When attempting to synthesize a group of studies using meta-analysis, it is reasonable to expect that the studies have enough in common to allow the data from those studies to be combined for statistical inference; however, it would be impractical to require that all studies in the group have identical true effect-sizes. It is impossible for independent studies to be identical in every aspect. Therefore, heterogeneity is likely to exist in many meta-analyses. The model that takes heterogeneity into account is the following random-effects meta-analysis models:

$$\hat{\beta}_k = \beta + b_k + \varepsilon_k, k = 1, 2, \dots, K, \quad (7)$$

where for study K, $\hat{\beta}_k$ represents the observed effect-size and β the global population effect-size. b_k is now the random-effects with mean 0 and variance τ^2 representing the between-study heterogeneity, and ε_k is the sampling error with mean 0 and variance $\hat{\sigma}_{\beta_k}^2$. It is assumed that b_k and ε_k are independent and follow normal distributions $N(0, \tau^2)$ and $N(0, \hat{\sigma}_{\beta_k}^2)$, respectively. Let $\beta_k = \beta + b_k$, $k = 1, 2, \dots, K$.

Then the random-effects model given in Eq. 7 can be simplified as:

$$\hat{\beta}_k = \beta_k + \varepsilon_k, \quad (8)$$

where β_k represents the true effect-size for study K. All β_k ($k = 1, 2, \dots, K$) are random samples from the same normal population,

$$\beta_k \sim N(\beta, \tau^2) \quad (9)$$

rather than being a constant in the fixed-effects MA in Eq. 2. Further, the marginal variance of $\hat{\beta}_k$ is given by,

$$\text{Var}(\hat{\beta}_k) = \tau^2 + \hat{\sigma}_{\beta_k}^2, \quad (10)$$

which is composed of two sources of variation, i.e. the between-study variance τ^2 and within-study variance $\hat{\sigma}_{\beta_k}^2$. If the between-study variance $\tau^2 = 0$, the random-effects MA models given in Eq. 7 would reduce to the fixed-effects MA models given in Eq. 2.

Similar to the fixed-effects MA models, the within-study variance $\hat{\sigma}_{\beta_k}^2$ can be obtained or calculated from each study K ($k = 1, 2, \dots, K$). However, the information for determining between-study variance τ^2 is often not available, and the methods commonly used for assessing between-study heterogeneity include the DerSimonian-Laird's method of moments (MM) described in the study DerSimonian and Laird,^[6] the maximum likelihood estimation (MLE) method described in the study by Hardy and Thompson,^[7] and the restricted maximum likelihood (REML) method described in the study by Raudenbush and Bryk.^[8] As the most commonly used estimator, MM is a distribution-free and non-iterative approach whereas both MLE and REML are parametric methods and need iteration for estimating τ^2 and the related meta-regression parameter β described in the section "Meta-regression."

The MM uses the Q-statistic for testing the assumption of homogeneity:

$$Q = \sum_{k=1}^K w_k (\hat{\beta}_k - \hat{\beta}_F)^2 \quad (11)$$

where $w_k = 1 / \hat{\sigma}_{\beta_k}^2$ is the weight from the Kth study, $\hat{\beta}_k$ is the Kth study effect-size, and $\hat{\beta}_F$ is the global overall effect estimated from Eq. 3. It can be seen that Q is calculated: (1) to compute the deviations of each effect-size from the meta-estimate and square them [i.e., $(\hat{\beta}_k - \hat{\beta}_F)$]; (2) to weight these values by the inverse-variance for each study; and (3) then to sum these values across all K studies to produce a weighted sum of squares to obtain the heterogeneity measure Q.

From Eq. 11, it can be shown that the expected value of Q is:

$$E(Q) = (K - 1) + U \times \tau^2 \quad (12)$$

$$\text{where } U = \sum_{k=1}^K w_k - \frac{\sum_{k=1}^K w_k^2}{\sum_{k=1}^K w_k}.$$

Under the assumption of no heterogeneity (all studies have the same effect-size), then τ^2 would be zero and $E(Q) = df = K - 1$. Based on this heterogeneity measure Q , the test of heterogeneity is conducted to address the null hypothesis that the effect-sizes β_k from all studies share a common effect-size β (i.e., the assumption of homogeneity) and then test this hypothesis where the test statistic is constructed using Q as a central χ^2 distribution with degrees of freedom of $df = K - 1$. However, a cautionary note is warranted—this χ^2 -test using the Q -statistic has poor statistical power to detect true heterogeneity for a meta-analysis with a small number of studies K , but excessive power to detect negligible variability with a large number of studies as discussed in the study by Harwell^[9] and Hardy and Thompson.^[7] Thus, a nonsignificant test using Q -statistic from a small number of studies can lead to an erroneous selection of a fixed-effects model when possible true heterogeneity exists among the studies, and vice versa. The inability to conclude statistically significant heterogeneity in a meta-analysis of a small number of studies at the 0.05 level of significance is similar to failing to detect statistically significant treatment-by-center interaction in an MRCT. In these settings, many analysts might choose to conduct the test of homogeneity at the 0.10 level as a means of increasing the power of the test.

From Eq. 12, the MM estimate of τ^2 can be shown as follows:

$$\hat{\tau}^2 = \max\left(0, \frac{Q - (K - 1)}{U}\right) \quad (13)$$

The truncation at zero in Eq. 13 ensures the variance estimate is nonnegative.

Therefore, the estimate of the global population effect-size in random-effects MA is given by:

$$\hat{\beta}_R = \frac{\sum_{k=1}^K w_k^* \hat{\beta}_k}{\sum_{k=1}^K w_k^*} \quad (14)$$

where $w_k^* = 1/(\hat{\sigma}_{\beta_k}^2 + \hat{\tau}^2)$. The variance of $\hat{\beta}_R$ is simply,

$$\text{Var}(\hat{\beta}_R) = 1/\sum_{k=1}^K w_k^*$$

and the 95% confidence interval can be constructed by

$$\hat{\beta}_R - z_{0.025} \sqrt{\text{Var}(\hat{\beta}_R)} \leq \beta \leq \hat{\beta}_R + z_{0.025} \sqrt{\text{Var}(\hat{\beta}_R)}.$$

The statistical test can be similarly formulated by:

$$z = \frac{\hat{\beta}_R - \beta}{\sqrt{\text{Var}(\hat{\beta}_R)}} \quad (15)$$

to be used to test $H_0 : \beta = 0$ in the random-effects MA framework.

Quantify Heterogeneity in Meta-Analysis

Although the Q -statistic can be used to test the existence of heterogeneity, it does not report the extent of such heterogeneity. Given this limitation of the Q -statistic, several indices are proposed to quantify heterogeneity, including the τ^2 , H , and I^2 indices.

The τ^2 Index

The τ^2 index is defined as the variance of the true effect-size as seen in the random-effects MA model given in Eq. 13. Since it is impossible to observe the true effect-size, we cannot calculate this variance directly, but we can estimate the variance from the observed data using Eq. 11 as follows:

$$\hat{\tau}^2 = \frac{Q - (K - 1)}{U} \quad (16)$$

which is the well-known DerSimonian-Laird method of moments for τ^2 in Eq. 13. Even though the true variance τ^2 can never be less than zero, the estimated variance $\hat{\tau}^2$ can sometimes be less than zero because of the sampling error leading to $Q < K - 1$. When this occurs, the estimated $\hat{\tau}^2$ is set to zero.

As used in the random-effects MA model, the τ^2 index is also an estimate for the between-studies variance in the meta-analysis.

The H Index

Another index or measure of heterogeneity is the H index, which was proposed in Higgins and Thompson^[10] and is defined as follows:

$$H = \sqrt{\frac{Q}{K - 1}} \quad (17)$$

The H index is based on the fact that when no heterogeneity exists, then $E[Q] = K - 1$. In this case, H should be 1.

The confidence interval for the H index is derived in Higgins and Thompson^[10] based on the assumption that the natural logarithm of $\ln(H)$ follows a standard normal distribution. Accordingly,

$$LL_H = \exp\{\ln(H) - |z_{\alpha/2}| \times SE[\ln(H)]\} \quad (18)$$

$$UL_H = \exp\{\ln(H) + |z_{\alpha/2}| \times SE[\ln(H)]\} \quad (19)$$

where LL and UL denote the lower- and upper-limits of the CI, $z_{\alpha/2}$ is the $\alpha/2$ -quantile of the standard normal

distribution, and $SE[\ln(H)]$ is the standard error of $\ln(H)$ and is estimated by:

$$SE[\ln(H)] = \begin{cases} \frac{1}{2} \frac{\ln(Q) - \ln(K-1)}{\sqrt{2Q - \sqrt{2K-3}}} & \text{if } Q > K \\ \sqrt{\frac{1}{2(K-2)} \left(1 - \frac{1}{3(K-2)^2}\right)} & \text{if } Q \leq K \end{cases} \quad (20)$$

Since $E(Q) \approx K - 1$ as seen in Eq. 12, the H index should be greater than 1 to measure the relative magnitude of heterogeneity among all studies included in the meta-analysis. If the lower limit of this interval is greater than 1, then H is statistically significant.

The I^2 Index

To measure the proportion of observed heterogeneity from the real heterogeneity, Higgins and Thompson^[10] and Higgins et al.^[11] proposed the I^2 index as follows:

$$I^2 = \left(\frac{Q - (K-1)}{Q} \right) \times 100\%, \quad (21)$$

which represents the ratio of excess dispersion to total dispersion and is similar to the well-known R^2 in classical regression that represents the proportion of the total variance that can be explained by the regression variables.

As suggested from Higgins et al.^[11] values of the I^2 index around 25%, 50%, and 75% could be considered as *low*-, *moderate*-, and *high*-heterogeneity, respectively. As noted in their article, about half of the meta-analyses of clinical trials in the *Cochrane Database of Systematic Reviews* have reported an I^2 index of zero, and the other half of reviewers have reported evenly distributed I^2 indices between 0% and 100%.

Mathematically, the I^2 index can be represented using the H index as follows:

$$I^2 = \frac{H^2 - 1}{H^2} \times 100\% \quad (22)$$

This expression allows us to use the results from the H index to give a confidence interval for the I^2 index using the expressions in Eqs. 18 and 19 as follows:

$$LL_{I^2} = \left[\frac{(LL_H)^2 - 1}{(LL_H)^2} \right] \times 100\%$$

$$UL_{I^2} = \left[\frac{(UL_H)^2 - 1}{(UL_H)^2} \right] \times 100\%$$

Since I^2 represents the percentage, any of these limits computed as negative is set to zero. In cases when the lower limit of I^2 is greater than zero, then the I^2 is considered to be statistically significant.

Meta-Regression

Although the random-effects meta-analysis model can account for between-study heterogeneity, this model cannot explain or explore how these heterogeneities originated relative to other study-level variables. When study-level variables—commonly called moderators—are available, meta-regression is used to investigate the association between these moderators and the reported effect-sizes. Meta-regression is in fact the typical weighted regression when study-level moderators are associated with the reported effect-sizes as the dependent variable and their variance is used as weights. From this viewpoint, meta-regression is merely typical multiple regression applied to study-level data, and therefore, the theory of regression can be directly applied to meta-regression.

The following introduces two types of meta-regression, which are built on the fixed-effects and random-effects MA models, respectively. Suppose that there are p moderators $X_1, X_2, \dots, X_p$ and K independent studies. The fixed-effects meta-regression model is given by:

$$\hat{\beta}_k = \beta_0 + \beta_1 x_{k1} + \dots + \beta_p x_{kp} + \epsilon_k \quad (23)$$

where $x_{k1}, \dots, x_{kp}$ ($k = 1, 2, \dots, K$) denote the observed values of the p moderators $X_1, X_2, \dots, X_p$ for study K and $\beta_0, \beta_1, \dots, \beta_p$ are regression coefficients. The effect-size $\hat{\beta}_k$ and sampling error ϵ_k have the same definitions as in fixed-effects MA models given in Eq. 2. The model assumes that the variation in effect-sizes can be fully explained by these moderators.

The random-effects meta-regression can be obtained by adding random-effects b_k to the fixed-effects model in Eq. 23:

$$\hat{\beta}_k = \beta_0 + \beta_1 x_{k1} + \dots + \beta_p x_{kp} + b_k + \epsilon_k, k = 1, 2, \dots, K$$

where b_k is assumed to be independent with a mean 0 and variance τ_2 . Unlike the fixed-effects meta-regression, where all variability in effect-sizes can be explained by the moderators $X_1, X_2, \dots, X_p$, the random-effects meta-regression assumes that the model can explain only part of the variation and the remaining variance can be accounted for by random-effects b_k .

Is is notable that the meta-regression technique is most appropriate when a meta-analysis includes a large number of studies. Further, because the moderators and the outcome in meta-regression are all study-level summary statistics (e.g., patient mean age, proportion of female patients), the relation between these moderators and the outcome might not directly reflect the relation between subject scores and subject outcomes, causing aggregation bias. Therefore, those conducting meta-regression should give careful consideration to the interpretation of the results.

META-ANALYSIS USING R

BCG Vaccine Clinical Trials

This section uses a dataset compiled from 13 clinical trials conducted to assess the efficacy of a BCG vaccine in the prevention of TB. The dataset has been used elsewhere to illustrate meta-analysis and meta-regression. For example, these data have been used by Everitt and Hothorn^[12] (see Table 12.2), Hartung et al.^[2] (see Table 18.8), Borenstein et al.^[3] (see Table 20.1) and Chen and Peace^[5] (see Table 7.1). In addition, the dataset has been used in the papers by van Houwelingen et al.^[13] to illustrate a tutorial in statistical analyses, and by Viechtbauer^[14] to provide an overview for those interested in learning how to conduct meta-analysis in R with *metafor* package. The source dataset was first reported in the study by Colditz et al.^[15]

Notably, the sources noted above vary in the numbers reported even though all used the same dataset from the same publications. The data tables reported from Everitt and Hothorn,^[12] Borenstein et al.,^[3] and Colditz et al.^[15] are the total cases in both the BCG test group and the control group. However, the dataset reported in van Houwelingen et al.^[13] and in Viechtbauer^[14] for the R *metafor* library are the numbers of TB “negative cases.” This entry uses the TB “negative case” data structure which is reproduced here for complete presentation in Table 1.

In this table, *author* denotes the authorship from the 13 studies, *year* is the publication year of these 13 studies, *tpos* is the number of TB-positive cases in the BCG vaccinated group, *tneg* is the number of TB-negative cases in the BCG vaccinated group, *cpos* is the number of TB-positive cases in the control group, *cneg* is the number of TB-negative cases in the control group, *ablat* denotes the absolute latitude of the study location (in degrees), and

alloc denotes the method of treatment allocation with three levels of random, alternate, or systematic assignment.

The purpose of the original meta-analysis was to quantify the efficacy of the BCG vaccine against TB, which was facilitated by a random-effects meta-analysis. The original study concluded that the BCG vaccine significantly reduced the risk of TB-negative in the presence of significant heterogeneity. The heterogeneity was partially explained by the study sites’ geographic latitudes. The following section uses this dataset to illustrate the meta-analysis procedures described in Section 2 with a step-by-step implementation in R.

Fixed-Effects and Random-Effects Meta-Analysis

Effect-Size Calculation

We illustrate the meta-analysis using the R package *metafor*. To use this package, the dataset must first be loaded into R using the following R code chunk:

```
# load the R library
> library("metafor")
# load the BCG data
> data("dat.bcg", package = "metafor")
```

To conduct a meta-analysis, we need to convert the 2×2 contingency table in Table 1 into study-specific effect-size (ES). As a typical ES, we use the log odds-ratio which can be specified as *measure* = “OR” in R function *escalc* which stands for “effect-size calculation” as shown in following R code chunk:

```
> dat = escalc(measure="OR", ai=tpos,
  bi=tneg, ci=cpos, di=cneg, data=dat.
  bcg, append = TRUE)
```

Table 1 Data from studies on efficacy of BCG vaccine for preventing TB

Trial	Author	Year	tpos	tneg	cpos	cneg	ablat	Alloc
1	Aronson	1948	4	119	11	128	44	Random

11	Comstock et al	1974	186	50448	141	27197	18	-0.3408	0.0125
12	Comstock & Webster	1969	5	2493	3	2338	33	0.4466	0.5342
13	Comstock et al	1976	27	16886	29	17825	33	-0.0173	0.0716

It can be found that 11 of 13 trials (except trials 8 and 12) have negative log odds-ratios, which indicate that the BCG vaccine reduced the risk of TB for these 11 studies, but not for the trials of 8 and 12. The statistical significance can be examined by constructing the t-statistic using the ratio of “yi” to the squared-root of “vi” or the 95% confidence intervals as shown in Fig. 1. Examining this figure, we can see that only studies 2, 3, 4, 6, 7, 10, and 11 (i.e., 7 out of 13) are statistically significant.

Fixed-Effects Meta-Analysis

The above ES calculation leads to meta-analysis of the 13 studies together. Assuming all 13 studies are homogenous,

the fixed-effects meta-analysis described in Section Fixed-Effects Meta-Analysis can be performed using R function “rma” as follows:

```
# Fixed-effects MA
> meta.FE = rma(yi, vi, data = dat,
  method="FE")
# Print the summary
> meta.FE
Fixed-Effects Model (k = 13)
Test for Heterogeneity: Q(df = 12)
= 163.1649, p-val < .0001
```

Fig. 1 Forest plot before/after meta-regression

Model Results:

```
estimate se      zval    pval   ci.lb   ci.ub
-0.4361 0.0423 -10.3190 <.0001 -0.5190 -0.3533
```

This shows that the estimated global log odds-ratio is -0.436 with a SE of 0.0423 and a p -value < 0.0001 . These values mean that when the 13 studies are analyzed together (i.e., meta-analysis), the global overall effect of the BCG vaccine is found to be statistically significant in preventing TB. However, the test of heterogeneity (i.e., $Q = 163.1649$ with $df = 12$, p -value < 0.0001 from χ^2 -test) is highly statistically significant, which indicates that the assumption of homogeneous studies in fixed-effects meta-analysis is not appropriate, and therefore, the random-effects meta-analysis should be explored.

Random-Effects Meta-Analysis

The DerSimonian-Laird random-effects meta-analysis models can be implemented easily as follows:

```
# Call 'rma' with method="DL" to fit the
random-effects MA
> meta.DL = rma(yi, vi, data = dat,
method="DL")
# Print the summary
> meta.DL
Random-Effects Model (k = 13; tau^2
estimator: DL)
tau^2 (estimated amount of total
heterogeneity): 0.3663 (SE = 0.2659)
tau (square root of estimated tau^2
value): 0.6053
I^2 (total heterogeneity / total
variability): 92.65%
H^2 (total variability / sampling
variability): 13.60
```

Model Results:

```
estimate se      zval    pval   ci.lb   ci.ub
-0.4361 0.1923 -10.3190 0.0001 -1.1242 -0.3706
```

The global overall estimate from the random-effects meta-analysis model is $\hat{\beta} = -0.747$ with $SE = 0.192$ and p -value $= 0.001$, which indicates the results of the 13 studies reach statistical significance, if meta-analyzed together. In this random-effects meta-analysis, the estimated between-study heterogeneity $\hat{\tau}^2 = 0.3663$ with $I^2 = 92.65\%$ and $H^2 = 13.60$ demonstrates highly and statistically significant heterogeneity. However, to explain this heterogeneity, we will need to use meta-regression.

Meta-Regression

To explain the heterogeneity, we can make use of the geographic latitude data that indicate the location where the clinical trials were conducted. This random-effects meta-regression can be implemented using the following R code chunk:

```
# random-effects meta-regression
> metaReg = rma(yi, vi, mods = ~ablat,
method="DL", data = dat)
# Print the meta-regression results
> metaReg
Mixed-Effects Model (k = 13; tau^2
estimator: DL)
tau^2 (estimated amount of residual
heterogeneity): 0.0480 (SE = 0.0451)
tau (square root of estimated tau^2
value): 0.2191
I^2 (residual heterogeneity /
unaccounted variability): 56.17%
H^2 (unaccounted variability / sampling
variability): 2.28
R^2 (amount of heterogeneity accounted
for): 86.90%
Test for Residual Heterogeneity: QE(df =
11) = 25.0954, p-val = 0.0088
Test of Moderators (coefficient(s) 2):
QM(df = 1) = 26.1628, p-val < .0001
```

Model Results:

```
estimate se      zval    pval   ci.lb   ci.ub
intrcpt  0.3030 0.2109  1.4370 0.1507 -0.1103  0.7163
ablat    -0.0316 0.0062 -5.1150 <.0001 -0.0437 -0.0195
```

As can be seen from the output, with only *ablat*, the estimated residual heterogeneity $\hat{\tau}^2$ dropped to 0.048 ($SE = 0.0451$) from the previous random-effect meta-analysis without *ablat* where the heterogeneity was estimated at 0.3663 . This change in estimates indicates that the moderator *ablat* itself accounts for $(0.3663 - 0.0480) / 0.3663 = 87\%$ of the total amount of heterogeneity, and the absolute latitude is significantly related to the effectiveness of the BCG vaccine in preventing TB, which can be quantified in the estimated meta-regression equation as follows:

$$\log(OR) = 0.3030 - 0.0316 \times ablat \quad (24)$$

The estimated equation and the entire meta-regression summary is graphically displayed in Fig. 2. In Fig. 2, the meta-regression in Eq. 24 is plotted using a solid line and its 95% CI bounds are plotted in dashed dots. The horizontal line from $OR = 0$ indicates no BCG vaccine effects. The

Fig. 2 Random-effects meta-regression for BCG data on OR on absolute latitude

13 studies are plotted in 13 solid dots where the sizes of the dots are proportional to their sample sizes.

Both this equation and Fig. 2 show that the BCG vaccine was more effective as the absolute latitude increased. When the *ablat* is less than 20 degrees and close to zero (i.e., a study performed closer to equator), the effect-size would be close to zero (as evidenced by the nonsignificant intercept parameter and Fig. 2, which means the vaccine had no real effect on prevention of TB). As *ablat* increases, say to latitude of 60 degrees, the log OR as calculated from Eq. 24 is -1.593 which corresponds to an OR of 0.20.

This property is further illustrated in Fig. 1, where the right side of the figure is the point estimate of log odds-ratio and the 95% CIs for each of the 13 studies. The middle part is a graphical representation of these 95% CIs in solid line segments. The shaded diamonds are the 95% CIs after the meta-regression adjustment. The three dark diamonds near the bottom of the figure are the 95% CIs for the random-effects meta-regression at three latitudes of 10, 30, and 60 degrees. We can see that at 10 degrees, the estimated log odds-ratio is -0.01 and the 95% CI is $(-0.32, 0.30)$, indicating that the tested BCG vaccine produced no statistically significant benefit.

CONCLUSION

This entry gave a detailed overview for the classical statistical meta-analysis including the fixed-effects and random-effects meta-analysis models. Linked with quantification of the heterogeneity in meta-analysis, the indices of τ^2 , H , and I^2 were introduced along with the meta-regression to take into account the between-study heterogeneity and variations from all studies in meta-analysis. To facilitate the understanding of meta-analysis techniques and for interested readers to use these models for their own meta-analysis, a real-world dataset is used as an example to illustrate how to do a meta-analysis by giving

a step-by-step implementation in R so that readers can follow the meta-analysis models and reuse the R programs for their own meta-analysis.

For ease of illustration, this entry focused on meta-analysis of two-arm clinical trials. Another direction for meta-analysis is to consider multiple-treatment comparisons or mixed-treatment comparisons, which are called network meta-analysis. Network meta-analysis combines multiple-treatment comparisons as a network to achieve a more statistically powerful analysis; therefore, network meta-analysis is a key tool for evidence-based biopharmaceutical research and development. Readers interested in network meta-analysis are referred to R package “netmeta” for more information and R implementations.

Abstract

This entry reviews general allocation strategies for building repeated measurement designs, provides simulations to illustrate the properties of adaptive designs, and details applications for this method.

Keywords: Evaluation function; Mean squared error (MSE); Multiple-objective design; Optimality criteria; Repeated measurement design; Response-adaptive design (RAD); Self and mixed carryover effects model.

INTRODUCTION

Drug development is complex and costly. It requires researchers to test the potential of numerous chemical compounds to treat the disease. Use of prior experiences and/or accumulated information can advance the development of clinical trial designs. Clinical designs can greatly assist in this pursuit, by utilizing past experiences to update the protocols of the trials continuously based on evidence.

When using response-adaptive designs (RADs), the trial is modified on the basis of available responses in order to achieve a specific goal. Response-adaptive allocation literature has a long history. Hu and Rosenberger^[1] raised important questions regarding response-adaptive randomization in a rigorous mathematical framework and systematically addressed various issues. RADs have traditionally been constructed to satisfy a single objective, for example, obtaining a precise estimate of a treatment effect,^[2] minimizing the number of subjects required for a study,^[3] or maximizing the allocation of subjects to beneficial treatments.^[4–6] More recently, Liang and Carriere^[7] studied an adaptive allocation strategy to construct multiple-objective repeated measurement designs, to increase estimation precision and treatment benefit by recognizing efficacy of treatments or treatment groups (sequences). In this chapter, we provide unified strategy to construct designs for both continuous and dichotomous outcomes.

This chapter is organized as follows. The section “Design Allocation Strategy” reviews the general allocation strategies for building repeated measurement designs. “Design Model” describes the application details of the general allocation rule for clinical trials with continuous and

dichotomous outcomes. “Simulations” presents the properties of the adaptive designs via simulations in practical two-treatment two- or three-period repeated measurement designs with continuous and dichotomous outcomes. Finally, we present our conclusions and suggestions for further work.

DESIGN ALLOCATION STRATEGY

To construct multiple-objective response-adaptive designs, we pre-specify N (total number of subjects) and λ , the percentage weight given to the primary objective, and then $1 - \lambda$ is the percentage weight given to a secondary objective. Here, the first objective may be the typical one, maximizing the information matrix, and the second objective may be to increase favorable treatment experiences in the trial. Depending on the nature of trials, these objectives can be revised.

Basically, the usual optimal design construction methods are advocated to adaptively determine the allocation rule for solving multiple objectives,^[2,8–10] as follows.

- Step 1: Choose a desired evaluation function g . Then, the first m ($m < N$) patients are randomly assigned to all possible treatments or treatment sequences.
- Step 2: Assuming that the l^{th} ($m + 1 \leq l \leq N$) patient will be treated by treatment sequence k , calculate the information matrix $\hat{A}_l^k$ based on first $l - 1$ patients' responses, and the evaluation function $g_{l-1,k}$ for each treatment sequence k , where the domain of k is all possible treatment sequences, to allocate the l^{th} patient.

Liang and Carriere^[7] have given some examples of defining evaluation functions for different types of outcomes. Without loss of generality, we assume that a higher value of $g_{l-1,k}$ indicates a better treatment sequence from this point forward.

Step 3: Choose the treatment sequence k^* from the s possible treatment sequences for the l^{th} patient, in such a way that

$$\Lambda(l, k^*) = \max_{k=1 \dots s} \Lambda(l, k)$$

where

$$\Lambda(l, k) = \lambda \frac{\Theta(\hat{A}_l^k)}{\Theta(\hat{A}_l^{(o)})} + (1 - \lambda) \frac{g_{l-1,k}}{g_{l-1,k_{l-1}^{(B)}}}. \quad (1)$$

Eq. 1 is called the selection criterion, which is designed to achieve two objectives by creating a balance between them. We choose the criterion in such a way that the first part aims to favor a treatment sequence that maximizes the information matrix measured by its determinant (D-optimality), trace (A-optimality), or maximum eigenvalue (E-optimality). The second part aims to favor a treatment sequence that gives the best performance on the evaluation function, among all of s treatment sequences. At each stage, one treatment sequence $k_l^{(o)}$ maximizes the optimality criterion, $\Theta(\cdot)$, and possibly another treatment sequence $k_{l-1}^{(B)}$ has the best value on the evaluation function, $g_{l-1,k}$. Prior to the experiment, investigators can choose a parameter $\lambda \in [0, 1]$ to weight and balance the two objectives. When $\lambda = 1$, we have the traditional criterion of a response-adaptive design problem. When $\lambda = 0$, the efficacy of the treatment sequence is the only concern. The choice is often driven by what the investigators want to emphasize. In situations where more than one treatment sequence achieves the maximum criterion score, we can randomly assign the l^{th} patient to one of them.

Step 4: Repeat steps 2 to 3 until all N patients have been allocated.

Note that the above adaptive approach is applicable to both discrete and continuous responses, under suitable model assumptions.

DESIGN MODEL

Continuous Outcomes

Traditionally, models for repeated measurement designs have used simple first-order carryover effects.^[11,12] Recently,

Afsarinejad and Hedayat^[13] proposed a model that allows for two different types of carryover effects from each treatment—the self and mixed carryover effects. They also studied optimal two-period repeated measurement designs with two or more treatments under a model with fixed subject effects. The model we consider is

$$y_{ijk} = \mu + \pi_i + \tau_{d_k[i,j]} + (1 - \delta_{ijk})\gamma_{d_k[i-1,j]} + \delta_{ijk}\phi_{d_k[i-1,j]} + \xi_{jk} + \varepsilon_{ijk} \quad (2)$$

where y_{ijk} denotes the response variable for the j^{th} subject given treatment sequence k in period i , $i = 1, 2, \dots, p$, $j = 1, 2, \dots, N_k$, $k = 1, 2, \dots, s$, p is the number of periods, N_k is the number of subjects given treatment sequence k , s is the number of treatment sequences, μ , π_i , ξ_{jk} , and ε_{ijk} are the overall mean, period, subject, and measurement error effects, respectively^[7]. Denote $d_k[i, j]$ as the treatment used for subject j given treatment sequence k in period i . Assume that ξ_{jk} and ε_{ijk} are mutually independent random effects with mean 0 and variance σ_ξ^2 and σ_ε^2 , respectively. Then $\tau_{d_k[i,j]}$ is the treatment effect of a treatment $d_k[i, j]$, and both $\gamma_{d_k[i-1,j]}$ and $\phi_{d_k[i-1,j]}$ represent carryover effects of a treatment $d_k[i-1, j]$ given in period $(i-1)$ into the next period for subject j given treatment sequence k with an indicator variable δ_{ijk} taking 1 if $d_k[i, j] = d_k[i-1, j]$ and 0 otherwise.

Thus, this model considers two different kinds of carryover effects: $\gamma_{d_k[i-1,j]}$ is the carryover effect of one treatment followed by a different treatment, called the *mixed carryover effect*, while $\phi_{d_k[i-1,j]}$ is the carryover effect of a treatment onto itself, called *self carryover effect*, with $\gamma_{d_k[0,j]} = \phi_{d_k[0,j]} = 0$. In following the steps in the section “Design Allocation Strategy”, calculating the information matrix and Criterion (1) is rather straightforward with continuous responses.^[7]

Dichotomous Outcomes

When the outcome is dichotomous, we use a multivariate Bernoulli model, and we assume that the responses are mutually independent. Let π_r be the success probability of treatment A in the r^{th} period, $r = 1, 2, \dots, p$; when $r = p+1, p+2, \dots, 2p$, let π_r be the success probability of treatment B in the $(r-p)^{\text{th}}$ period. To illustrate the adaptive strategy, we consider two treatment situations.

To allocate the l^{th} patient (or sometimes called the l^{th} stage), denote N_{kl} the number of subjects receiving treatment sequence k , where $k = 1, 2, \dots, 2^p$. $S_l = (S_{1A|}, \dots, S_{pA|}, S_{1B|}, \dots, S_{pB|})^T$, where S_{itl} denotes the number of successes of treatment t in the i^{th} period, where $i = 1, 2, \dots, p$ and $t = A$ or B . For example, $S_{1A|}$ represents the number of successes of A in the first period at the l^{th} stage. Let $S_l[r]$ be the r^{th} element of S_l , where $r = 1, 2, \dots, 2p$.

The likelihood function based on the first l patients is then

$$L_l = \prod_{r=1}^6 \pi_r^{S_l[r]} (1 - \pi_r)^{(N_{l_l}[r] - S_l[r])}$$

where if $1 \leq r \leq p$, $N_{l_l}[r]$ denotes the total number of patients receiving treatment A in the l^{th} period; if $p+1 \leq r \leq 2p$, $N_{l_l}[r]$ denotes the total number of patients receiving treatment B in the $(r-p)^{th}$ period. For example of a two-treatment three-period case with treatment sequences AAA, AAB, ABA, ABB, BBB, BBA, BAB, and BAA, they are

$$\begin{aligned} N_{l_l}[1] &= N_{1l} + N_{2l} + N_{3l} + N_{4l}, \\ N_{l_l}[2] &= N_{1l} + N_{2l} + N_{7l} + N_{8l}, \\ N_{l_l}[3] &= N_{1l} + N_{3l} + N_{6l} + N_{8l}, \\ N_{l_l}[4] &= N_{5l} + N_{6l} + N_{7l} + N_{8l}, \\ N_{l_l}[5] &= N_{3l} + N_{4l} + N_{5l} + N_{6l} \quad \text{and} \\ N_{l_l}[6] &= N_{2l} + N_{4l} + N_{5l} + N_{7l}. \end{aligned}$$

Let $N_{l_l} = (N_{l_l}[1], N_{l_l}[2], \dots, N_{l_l}[6])^T$.

The log-likelihood function ℓ_l becomes

$$\ell_l \propto \sum_{r=1}^6 (S_l[r] \log \pi_r + (N_{l_l}[r] - S_l[r]) \log(1 - \pi_r)).$$

The expected Fisher information matrix up to the l^{th} patient, A_r , which is a 6×6 diagonal matrix, becomes

$$A_l = \text{Diag} \left(E \left(\frac{S_l[r]}{\pi_r^2} + \frac{N_{l_l}[r] - S_l[r]}{(1 - \pi_r)^2} \right) \right)$$

where $r = 1, 2, \dots, 6$.

It is easy to show that the maximum likelihood estimation of unknown parameter π_r at stage l is obtained as $\hat{\pi}_r = \frac{S_l[r]}{N_{l_l}[r]}$, where $r = 1, 2, \dots, 6$.

Result 1: In two-treatment three-period repeated measurement designs with eight possible treatment sequences: {AAA, AAB, ABA, ABB, BBB, BBA, BAB, BAA} the expected Fisher information matrix on the $(l+1)^{th}$ stage is as follows. Given the history by l patients and under the assumption that the $(l+1)^{th}$ patient receiving treatment sequence k , $k = 1, 2, \dots, 8$,

$$A_{l+1}^k = \text{Diag} \left(\frac{S_{l+1}[r]}{\pi_r^2} + \frac{N_{l+1}[r] - S_{l+1}[r]}{(1 - \pi_r)^2} \right)$$

where $S_{l+1} = S_l + \text{Diag}(\pi \times \mathbf{u}_k)$, $\pi = (\pi_1, \pi_2, \dots, \pi_6)^T$, $N_{l+1} = N_{l_l} + \mathbf{u}_k^T$, $S_{l+1}[r]$ and $N_{l+1}[r]$ are the r^{th} element of S_{l+1} and N_{l+1} , respectively, and $\mathbf{u}_k$ is the k^{th} row vector of the matrix $\mathbf{U}$ defined below

$$\mathbf{U} = (\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_8)^T = \begin{pmatrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 \\ 0 & 0 & 1 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 1 & 0 & 0 \end{pmatrix}$$

$r = 1, 2, \dots, 6.$

This result can be generalized to apply to a multi-period situation, with $\mathbf{u}_k = (d(1, k), \dots, d(2p, k))$. When $1 \leq r \leq p$, $d(r, k) = 1$ if the treatment in the r^{th} period of the treatment sequence k is the treatment A; $d(r, k) = 0$, otherwise. When $p+1 \leq r \leq 2p$, $d(r, k) = 1$ if the treatment in the $(r-p)^{th}$ period of the treatment sequence k is the treatment B; $d(r, k) = 0$, otherwise. And $k = 1, 2, \dots, 2^p$, $r = 1, 2, \dots, 2p$.

In the spirit of the play-the-winner principle, an evaluation function is defined as the average number of successes for each treatment sequence, that is,

$$g_{kl} = \frac{\mathbf{u}_k \times S_l}{N_{kl}}$$

where $k = 1, 2, \dots, 8$, and $\mathbf{u}_k$ as defined in *Result 1* above.

For a given value of λ , under the optimality criteria of the estimated information matrix, $\Theta(\cdot)$, we choose a treatment sequence k^* to the $(l+1)^{th}$ patient by maximizing Λ ,

$$\Lambda = \lambda \frac{\Theta(\hat{A}_{l+1}^k)}{\Theta(\hat{A}_{l+1}^{(O)})} + (1 - \lambda) \frac{g_{l,k}}{g_{l,k_l^{(B)}}}$$

where $\Theta(\cdot)$, $k_l^{(O)}$ and $k_l^{(B)}$ are defined as in the section “Design Allocation Strategy”. Liang and Carriere^[14] give more details on the response adaptive construction for repeated measurement designs with dichotomous outcomes.

SIMULATIONS

We construct response-adaptive two-treatment two- and three-period repeated measurement designs. To assess the efficiency of an adaptive design, a matrix of mean squared error (MSE) for θ is computed

$$MSE = E[(\hat{\theta} - \theta)(\hat{\theta} - \theta)^T],$$

where θ is a vector of parameters of interest, and $\hat{\theta}$ is an estimate of θ .

In simulation studies, MSE is estimated by

$$MSE = \frac{\sum_{b=1}^B (\hat{\theta}^{(b)} - \theta)(\hat{\theta}^{(b)} - \theta)^T}{B},$$

where $\hat{\theta}^{(b)}$ is a maximum likelihood estimator of θ obtained in the b^{th} simulation run for the total B number of simulations.

Denote MSE_1 as the matrix of MSE for a proposed adaptive design and MSE_0 as the matrix for a reference design. Based on A-, D-, or E- optimality criteria,^[14] the relative efficiency (RE) of the adaptive design compared with the reference design. When $RE = a > 1$, the adaptive design is $(a - 1) \times 100\%$ more efficient than the reference design. When $RE = a < 1$, the adaptive design is only $a \times 100\%$ as efficient as the reference design.

Next we consider the situation for continuous and dichotomous outcomes, respectively. We consider $\lambda = 1, 0.9, 0.7, 0.3$, and 0 , and $N = 10$ (or 12), $40, 80$, and 100 . To smooth out the randomness, we report the average allocation results to treatment sequences from 5,000 repetitions. In addition, we compare the adaptive designs with fixed optimal designs using the relative efficiency. The computations were done in R version 2.6.2 (The R Foundation for Statistical Computing, Vienna, Austria, 2008).

Continuous Outcomes

We assume that $\sigma_\xi^2 = 2, \sigma_\epsilon^2 = 1$, and $\mu = 100$. For two-period three-period designs, there are four possible treatment sequences: AA, AB, BA , and BB . We consider two sets of parameters: (i) $\pi = \tau = \gamma = \phi = 0$ (no treatment difference); and (ii) $\pi = \tau = \phi = 2.5, \gamma = -2.5$ (for treatment performance in decreasing order from best to worst: AA, BA, AB , and BB). π, τ, γ and ϕ are the period effect contrast, direct treatment effect contrast, mixed carryover effect contrast, and self carryover effect contrast, respectively. For three-period designs, there are eight possible treatment sequences: $AAA, AAB, ABA, ABB, BBB, BBA, BAB$, and BAA . Similar to the two-period case, we consider two sets of parameters as well: (i) $\pi_2 = \pi_3 = \tau = \gamma = \phi = 0$ (no treatment difference); and (ii) $\pi_2 = \pi_3 = \tau = \phi = 2.5, \gamma = -2.5$ (with treatment difference), where π_2 and π_3 are dummy variables for the second- and third-period effects, respectively.

Two-Treatment Two-Period Designs

Four different treatment sequences are available for assignment. Suppose the first four patients are assigned equally to the four sequences, and the rest of the patients are to be allocated adaptively.

Table 1 shows the average number of patients assigned to each of the four treatment sequences. When there is no treatment difference, the columns I in Table 1 show that for all combinations of N and λ values, the adaptive allocation rule assigns an approximately equal number of subjects to each of the four treatment sequences, as expected, leading to the usual optimal four-sequence two-period design. When there is a treatment difference, the rule again assigns

an equal number of subjects to each of the four treatment sequences if $\lambda = 1$. This is similar to the traditional fixed optimal design. This is because estimation precision is the only consideration when $\lambda = 1$. When $\lambda < 1$, more patients are assigned to treatment sequence AA , which is the best combination setting. The rest of the patients, in decreasing order, receive treatments BA, AB , or BB , consistent with the setting.

Estimation of each parameter of interest with its standard error (not shown) indicates that in all cases the estimated values are very close to the true values of the parameters, and behave consistently as expected for increasing λ and N , allowing a tradeoff between treatment benefit and statistical optimality.

Two-Treatment Three-Period Designs

In two-treatment three-period designs, eight different treatment sequences are available for assignment. At the initial stage, eight patients are assumed to enter in the study, one for each treatment sequence. For $\pi_2 = \pi_3 = \tau = \gamma = \phi = 0$, since there are no treatment advantage, the columns I in Table 2 show that adaptive designs assign an approximately equal number of subjects to each of the eight treatment sequences when $\lambda = 0$. When $\lambda = 1$, adaptive designs assign an approximately equal number of subjects to a dual block (a treatment sequence and its dual with treatments in a reverse order), and more subjects are given to ABB and its dual, which the fixed optimal design uses for comparing two treatments under the traditional model. However, adaptive designs use six of the eight sequences rather uniformly.

When treatment differences are present, the mean vector of each treatment sequence, in decreasing order, is AAA, BAA, AAB (equivalently, ABA), BAB (equivalently, BBA), ABB , and BBB . Table 2 shows that, when $\lambda = 1$, adaptive designs assign an approximately equal number of subjects to a dual block, and more subjects are given to ABB and its dual. However, as $\lambda < 1$ and decreasing, adaptive designs assign more subjects to the best treatment sequence AAA and fewer subjects to the worst treatment sequence BBB . This is consistent with the setting. Similar to the two-period case, the allocation is rapidly skewed as λ decreases. When treatment differences are present, the impact of using low λ is evident. If the emphasis is placed on increasing the treatment benefit ($\lambda = 0$), Design AAA is optimal, followed by BAA .

Figure 1 shows the estimated relative efficiency (RE) of adaptive designs relative to the reference design using two sequences ABB and its dual, the popular fixed optimal design (under the traditional model) for estimating $\theta = (\tau, \gamma, \phi)^T$ under A-, D-, and E-optimality, and for estimating the treatment contrast τ , respectively. Adaptive design is shown more efficient than the reference design if $RE > 1$. Fig. 1 illustrates that response-adaptive designs are more efficient than the traditional design for large λ under

Note: Entries are based on 5,000 computer replications under two-treatment three-period repeated measurement designs with $\pi_2 = \pi_3 = \tau = \gamma = \phi = 0$ (columns I) and $\pi_2 = \pi_3 = \tau = \phi = 2.5$, $\gamma = -2.5$ (columns II) respectively, with $\sigma_\xi^2 = 2$, $\sigma_\varepsilon^2 = 1$, and $\mu = 100$.

Fig. 1 Relative efficiencies of adaptive two-treatment three-period designs: continuous outcomes

Note: The fixed design *ABB/BBA* is the reference design. Relative efficiencies in the upper row are calculated by using 5,000

computer replications with $\pi_2 = \pi_3 = \tau = \gamma - \phi = 0$; the bottom row with $\pi_2 = \pi_3 = \tau = \phi = 2.5$, $\gamma = -2.5$. And in all cases, we assume

$\sigma_\epsilon^2 = 2$, $\sigma_\tau^2 = 1$, and $\mu = 100$. $\theta = (\tau, \gamma, \phi)^T$. Since Design *ABA/BAB* cannot estimate the self carryover effect contrast $\left(\varphi = \frac{\phi_A - \phi_B}{2}\right)$, the efficiency is compared only for the direct treatment effect contrast $\left(\tau = \frac{\tau_A - \tau_B}{2}\right)$

all three optimality criteria. However, when $\lambda = 0$, adaptive designs are generally less efficient in terms of MSE. When a treatment effect is absent (upper row of Fig. 1), adaptive designs with $\lambda = 0$ utilize all possible treatment sequences equally (Table 2), which apparently reduces design efficiency; when a treatment effect is present (bottom row of Fig. 1), adaptive designs with $\lambda = 0$ use treatment sequence *AAA* heavily, followed by *BAA* and the unbalance clearly reduces the design efficiency, measured by MSE, although it is the best for estimating θ .

For estimating the direct treatment contrast, the design using *ABA* and *BAB* is the best because it is the optimal design under model (2)^[13]. However, this design cannot estimate self-carryover effects. Nonetheless, adaptive designs with a large value of λ are nearly as efficient as the fixed design (Fig. 1, panel d), while also taking the treatment performance into consideration. In general, using a large λ has no real consequences for the traditional notion of design efficiency, especially when the sample size is large. Use of $\lambda = 0$ has low efficiency relative to the reference

Note: Entries are based on 5,000 simulations with $\pi_r = 0.5, r = 1, 2, 3, 4$ (columns I) and $\pi_1 = 0.5, \pi_2 = 0.6, \pi_3 = 0.4$, and $\pi_4 = 0.5$ (columns II).

design, as N increases. These extreme results are due to implementing an objective while the efficiency is measured by a MSE, different from a measure of treatment efficacy.

Dichotomous Outcomes

Based on the multivariate Bernoulli model as described in section “Dichotomous Outcomes”, we construct response-adaptive two-treatment two-and three-period repeated measurement designs. We note here that the literature is sparse on optimal design methodologies for dichotomous responses. Clinical trials with an interest in binary or nominal outcome measurements have adopted optimal designs constructed for continuous responses. Various related research have dealt with how to efficiently analyze binary data upon adopting the traditional optimal design constructed for continuous responses under assumptions, inappropriate for actual measurements of interest. This chapter examines the merits of such approaches and construct adaptive designs, which are the most efficient under a given setting.

For two-period designs, the two sets of parameters are: (i) $\pi_r = 0.5$, for $r = 1, 2, 3, 4$ (no treatment difference); and (i) $\pi_1 = 0.5, \pi_2 = 0.6, \pi_3 = 0.4$, and $\pi_4 = 0.5$ (with treatment difference). For three-period designs, the two sets of parameters are: (i) $\pi_r = 0.5, r = 1, 2, \dots, 6$ (no treatment difference);

and (ii) $\pi_1 = 0.5, \pi_2 = 0.6, \pi_3 = 0.7, \pi_4 = 0.4, \pi_5 = 0.5$, and $\pi_6 = 0.6$ (with treatment difference). We assume that at the initial stage four patients were assigned for two-period designs and eight patients were assigned for three-period designs, one for each of the treatment sequences. We then consider allocating the rest of the patients adaptively.

Two-Treatment Two-Period Designs

Table 3 summarizes the estimated average number of patients receiving each treatment sequence based on the 5,000 simulation results. We can see that in the case of no treatment effect (columns I), the strategy assigns an equal number of subjects to a treatment sequence and its dual when $\lambda = 1$, with a slight preference to treatment sequences AA and BB , indicating no need for complex administration in the absence of treatment effects. When $\lambda < 1$, an approximately equal number of subjects is assigned to each of the four treatment sequences.

When there are treatment effects with $\lambda = 1$, the patterns are similar to the equal success probability case, with equal numbers of subjects to a dual block, allocating more subjects to treatment sequences AA and BB . However, when $\lambda < 1$, the adaptive design successfully assigns more patients to the best treatment sequence, which is a treatment

Fig. 2 Relative efficiency of θ for two-period two-treatment designs: binary outcome

Note: $\theta = (\pi_1, \pi_2, \pi_3, \pi_4)^T$. The fixed design $AB/BA/AA/BB$ is the reference design. Relative efficiencies are calculated on the basis of 5,000 simulations with $\pi_r = 0.5, r = 1, 2, 3, 4$ (upper row), and $\pi_1 = 0.5, \pi_2 = 0.6, \pi_3 = 0.4$, and $\pi_4 = 0.5$ (bottom row)

sequence AA followed by BA, AB and BB , even when sample size is small (e.g., $N = 12$). In addition, as N increases, the proportion of patients receiving the best treatment increases; whereas the proportion of patients receiving the worst treatment (BB) decreases. But the allocation results are more or less uniform unlike the continuous data case for the treatment effect setting considered.

Figure 2 illustrates the relative efficiency of the adaptive design to the reference design (the fixed optimal design for continuous data). Again we see that the design with a large λ serves both purposes quite well. Designs with a small value of λ are not efficient according to the conventional measure, but are no doubt the best strategy under another measure. Adopting the fixed optimal design for continuous responses will clearly be a misleading strategy.

The success probabilities of treatments in different periods and the estimation precision are also calculated for both equal and unequal treatment cases. Although not shown, they both show that the spread of the estimates of π_r decreases when the total number of patients increases, consistent with the setting.

Two-Treatment Three-Period Designs

Again, we observe that the similar assignment of patients is observed as in the continuous case, but in a lesser degree (Table 4). When all treatments are equally effective with

$\pi_r = 0.5, r = 1, 2, \dots, 6$ and when $\lambda < 1$, an approximately equal number of patients are assigned to each treatment sequence. When $\lambda = 1$, an equal number of patients are assigned to dual blocks with treatment sequences ABB and its dual having slightly more patients than other blocks, similar to the continuous case, but in a much less degree. When the success probabilities are not equal with $\pi_1 = 0.5, \pi_2 = 0.6, \pi_3 = 0.7, \pi_4 = 0.4, \pi_5 = 0.5$, and $\pi_6 = 0.6$, adaptive designs still use all eight sequences rather significantly. However, the impact of using low λ is not as pronounced as in the continuous case. Nonetheless, if the emphasis is placed on increasing the treatment benefit ($\lambda = 0$), it is best to allocate more to AAA , followed by BAA , and BBB is the worst, as it is the least effective treatment sequence.

These findings are evident in the relative efficiencies against the fixed optimal design with sequences ABB and BAA with an equal number of subjects per treatment sequence. Figure 3 illustrates the relative efficiency of the adaptive and reference designs under the A-, D-, and E- optimality, respectively. Similar to the two-period designs, the adaptive design with $\lambda < 1$ has low efficiency compared to the reference design. However, since the reference design is not necessarily the optimal choice in this situation, our conclusion is such that clinical trials must be carefully planned with a clear idea on not only the covariance structure^[12] but also the type and scale of outcome measurements desired and the trial objectives.

Note: Entries are based on 5,000 simulations with $\pi_r = 0.5, r = 1, 2, \dots, 6$ (columns I) and $\pi_1 = 0.5, \pi_2 = 0.6, \pi_3 = 0.7, \pi_4 = 0.4, \pi_5 = 0.5$ and $\pi_6 = 0.6$ (columns II).

**Fig. 3** Relative efficiency of θ for three-period two-treatment designs: binary outcome

Note: $\theta = (\pi_1, \pi_2, \pi_3, \pi_4, \pi_5, \pi_6)^T$. The fixed design ABB/BAA is the reference design. Relative efficiencies are calculated on the basis of 5,000 simulations with $\pi_r = 0.5, r = 1, 2, \dots, 6$ (upper row) and $\pi_1 = 0.5, \pi_2 = 0.6, \pi_3 = 0.7, \pi_4 = 0.4, \pi_5 = 0.5$ and $\pi_6 = 0.6$ (bottom row)

CONCLUSIONS

In this paper, we discussed the design allocation strategy to construct adaptive repeated measurement designs with both continuous and dichotomous responses/outcomes. We provide a detailed allocation rule for constructing practically useful repeated measurement designs adaptively for two-treatment and two-and three-period trials. We demonstrated that, as expected, the adaptive designs may not be as efficient as the fixed designs in terms of the mean squared error, but they successfully allocate more patients to better treatment sequences, no doubt the best strategy depending upon the study goals (Tables 1 to 4). In dichotomous outcome case, adaptive designs use all treatment sequences and the clinical trials simply adopting the conventional fixed optimal designs constructed for continuous responses may fail to achieve the study goal.

The investigator can predetermine the value of λ to balance the two objectives of increasing estimation precision and decreasing the proportion of patients receiving inferior treatments. A large value of λ places relatively heavy emphasis on the estimation precision. When $\lambda = 1$, the allocation rule becomes the usual response adaptive design as considered by other researchers.^[2] A small value of λ emphasizes the performance/benefit of the treatment. When $\lambda = 0$, the allocation rule becomes a typical play-the-winner rule.^[4] In addition, our simulated experiments show that the design with a high value of $\lambda < 1$ can result in allocating patients to effective treatment sequences without much loss of estimation precision.

The allocation rule can be generalized to construct adaptive t -treatment p -period repeated measurement designs. The main challenge is to narrow down the number of treatment sequences out of t^p possibilities, which may increase substantially as the number of treatments and periods increase. We may wish to keep the trials manageable by reducing the number of sequences, although this choice has the danger of possibly omitting some relevant sequences.

The value of λ can be chosen by investigators and is used to balance the two objectives of increasing estimation precision and decreasing the proportion of patients

receiving inferior treatment sequences. We find that design efficiency is a skewed function of λ that decreases sharply as λ decreases.

Clinical Trials: Selection of Control

Irving K. Hwang

Irving Consulting Group, Pluckemin, New Jersey, U.S.A., and University of Medicine and Dentistry of New Jersey (UMDNJ), New Brunswick, New Jersey, U.S.A.

Abstract

This entry discusses the importance of a control group or placebo in a clinical trial by presenting historical information and statistical indicators supporting their importance, and also offers useful alternatives and design modifications.

INTRODUCTION

Why is control necessary in clinical trials? The rationale is being well documented in ICH E-10 Guidance—Choice of Control Group and Related Design Issues in Clinical Trials.^[1] First, the control serves as a comparator that allows for discrimination of patient outcomes (changes in symptoms, signs, morbidity, or mortality) caused by the test treatment from outcomes caused by other factors, such as the natural progression of the disease, patient and/or investigator expectations, or other treatment. The experience gained on control provides the critical information, if the patients had not been treated with the test treatment or if they had been treated with a different treatment (e.g., a standard effective drug). Second, the inclusion of control can minimize bias through randomization and blinding. “Bias,” as defined in ICH E9 Guidance—Statistical Principles for Clinical Trials,^[2] means the systematic tendency of any aspects of the design, conduct, analysis, and interpretation of the results of clinical trials to make the estimate of a treatment effect deviate from its true value.

Control can be “historical” or “concurrent.” A historical control is a control selected from a defined patient population in a similar group of patients studied in historical trials. The patient population may no longer be the same due to medical care advancement and life style changes via health awareness. A concurrent control is one selected from the same patient population as the test treatment group and treated in the same trial concurrently in adherence to the study protocol. To ensure that the test and control groups are comparable at the trial start, randomization is usually used to minimize the chance of patient selection bias. To ensure that the test and control groups are similarly treated and evaluated during the study, blinding is usually used to minimize the treatment and evaluation bias. Whether a trial design includes these features is a critical determinant of its quality and integrity, especially for a Phase IIb–III confirmatory trial.

TYPES OF CONTROLS

As depicted in ICH E-10, controls in clinical trials can be classified on the basis of the treatment received and whether the test and chosen control groups are treated concurrently vs. externally/historically. There are generally five types. The first four (i.e., no treatment control, placebo control, active control, and dose–response control) are concurrent controls where the test and control groups are selected from the same patient population and treated concurrently usually via randomization of treatments. A variation of the four concurrent controls on the treatment received is multiple control (e.g., include both placebo and active controls in a single trial). The fifth type is external/historical controls. Because of lack of randomization and patient comparability of the test and control groups and its inability to minimize bias, this type of control is used only in exceptional cases. The five types of controls are no-treatment concurrent control, placebo concurrent control, active concurrent control, dose–response concurrent control, and external (historical) control.

No-Treatment Concurrent Control

In a no-treatment controlled trial, patients are usually randomly assigned to test treatment or no study treatment, e.g., test treatment vs. surgery or watchful waiting. Patients and investigators are not blinded to treatment assignment. Because the trial cannot be fully blinded, this can affect all aspects of the trial, including patient retention, patient management, and all aspects of endpoint assessment. However, it is often possible to have a blinded observer/rater conduct the endpoint assessment. This blind-observer approach should always be considered in trials that cannot be blinded, but it does not solve the other problems associated with knowing the treatment assignment such as investigator and/or patient expectation.

Placebo Concurrent Control

The placebo-controlled, double-blind trial has been the “gold” standard in drug development for many decades. The utilities of placebo-controlled trials are well established. In this design, patients are randomly assigned to a test drug or to an identical-appearing inactive drug (i.e., placebo). A placebo is a “dummy” drug that appears as identical as possible to the test drug with respect to physical characteristics such as color, weight, taste, and smell, but it does not contain the test drug or any other active ingredient of drugs. Such trials are almost always double-blind, with both patients and investigator unaware of treatment assignment. The treatments can be titrated or given at one or multiple, fixed doses. The placebo concurrent control design, by including a group that receives a dummy treatment, via randomization and blinding, controls for the so-called “placebo” effect. Simply, the placebo effect indicates improvement in a patient resulting from being treated other than from the true pharmacologic effect of an active drug. Therefore, the use of placebo concurrent control will be able to separate the true pharmacologic effect of the test drug from the other confounded effects (e.g., natural progression of the disease, regression to the mean, patient and/or investigator expectation, the effect of being treated in a trial, and subjectiveness of diagnosis/assessment). Placebo-controlled trials also have the ability to distinguish adverse effects caused by a drug from those resulting from underlying disease or intercurrent illness. The placebo-controlled trial, using randomization and blinding, generally minimizes patient and investigator bias. However, use of a placebo control may raise problems of ethics, acceptability, and feasibility, when an effective treatment is available for the condition (e.g., mortality and/or irreversible morbidity) under study. It is often possible to address the ethical or practical limitations of placebo-controlled trials by using modified study designs such as inclusion of multiple doses of the test drug or a known active-control drug, including the use of a pseudo-placebo (an ineffective low-dose, active-control drug).

Active Concurrent Control

An active-controlled (positive-controlled) trial is one in which a test treatment is compared with a known effective active treatment. Active-controlled trials have two distinct objectives with respect to demonstrating efficacy: (1) to demonstrate efficacy by showing superiority of the test treatment to the active-control treatment or (2) to show efficacy of the test treatment by showing it is non-inferior or equivalent to a known effective treatment. In an active (positive)-controlled trial, patients are randomly assigned to the test treatment or to an active-control treatment. Such trials are usually double-blind via the use of double dummies, but this is not always feasible. Many oncology trials, e.g., are difficult or impossible to blind

because of different regimens, routes of administration, and toxicities. Active-controlled trials are generally considered to pose fewer ethical and practical problems than placebo-controlled trials because all patients receive active treatment. Active-controlled trials also can, if properly designed, provide information about relative efficacy. The most crucial design question for an active-controlled trial is whether the trial is intended to show superiority or to show noninferiority/equivalence. When this design is used to show superiority of test treatment to an active-control drug, the approach is straightforward like the placebo-controlled trials. When superiority (significant difference between the test and active-control treatments) is shown, “assay sensitivity,” as defined in ICH E-10, of the trial is established, and efficacy of the test treatment is demonstrated. However, when it is used to show noninferiority/equivalence of the test treatment to an active-control treatment, assay sensitivity will need special consideration; it cannot be demonstrated directly, but rather deduced via “historical evidence of sensitivity-to-drug-effects” and “appropriate trial conduct,” as they are well addressed in ICH E-10. The discussion of these important issues will be deferred to the next section.

Dose–Response Concurrent Control

In a randomized, fixed-dose, dose–response-controlled trial, patients are randomized to one of several fixed-dose test treatment groups via titration or fixed dosing. Dose–response trials are usually double-blind. Dose–response trials are carried out to establish the relation between dose and efficacy and adverse effects and/or to demonstrate efficacy. Evidence of efficacy could be based on significant differences in pairwise comparisons between dosing groups or between dosing groups and placebo, or on evidence of a significant positive trend with increasing dose, even if no two groups are significantly different. In addition to fixed-dose test treatment groups, it may include a placebo (zero dose) and/or fixed-dose active-control treatment groups. A potential problem is that a positive dose–response trend (i.e., a significant regression of the response on dose), without significant pairwise differences, can establish test treatment efficacy, but may leave uncertainty as to which doses (other than the maximum dose) are actually effective.

External (Historical) Control

An external- or historical-controlled trial compares a group of patients receiving the test treatment with a group of patients external to the study, rather than to an internal control group consisting of patients from the same patient population randomly assigned to a different treatment. The external (historical) control can be a group of patients treated at an earlier time (historical control) or a group treated during the same time period but in a

different setting (external control). Lack of randomization and inability to minimize bias, the utilities of external/historical control are generally limited.

ASSAY SENSITIVITY, HISTORICAL EVIDENCE OF SENSITIVITY-TO-DRUG-EFFECTS, AND NONINFERIORITY MARGIN

As defined in ICH E-10, assay sensitivity is a property of a clinical trial defined as the ability to distinguish an effective treatment from a less effective or ineffective treatment. Assay sensitivity is important in any trial but has different implications for trials intended to demonstrate superiority vs. noninferiority/equivalence. (Note that most active-controlled equivalence trials are practically noninferiority trials intended to establish the efficacy of a new treatment. The new treatment can be shown noninferior as well as superior to the active-control drug, not limited to equivalence per se. Hence, the term of equivalence will be dropped hereafter in this document.) In the superiority trial setting whether the control is placebo or an active drug, assay sensitivity refers to the ability of a specific trial to detect a difference between treatments, if one exists. For active-controlled noninferiority trials, assay sensitivity requires the presence of a control drug effect of a minimum size so that a specific trial, properly designed and conducted, has the ability not to falsely conclude an ineffective treatment noninferior. Because the actual effect size of the active control in the trial is not measured relative to placebo, the presence of assay sensitivity must be deduced. If a trial intended to demonstrate efficacy by showing superiority of a test treatment to control lacks assay sensitivity, it will fail to show that the test treatment is superior and will fail to lead to a conclusion of efficacy. In contrast, if a trial intended to demonstrate efficacy by showing a test treatment to be noninferior to an active control lacks assay sensitivity, the trial may find an ineffective treatment to be noninferior and could lead to an erroneous conclusion of efficacy. Therefore, when a finding of noninferiority is used as evidence of efficacy, the determination of assay sensitivity is critical. In this case, the evidence of assay sensitivity in the trial may be deduced from:

1. Historical evidence of sensitivity-to-drug-effects.

It means that similarly designed trials in the past regularly distinguished effective treatments from less effective or ineffective treatments. Historical evidence of sensitivity-to-drug-effects should be evaluated at the beginning of designing a noninferiority trial. Specifically, it should be determined that, in the specific therapeutic area under study, appropriately designed and conducted trials that used a well-defined dose of a specific active treatment, or other treatments with similar effects, reliably showed an effect of at least a minimum size.

2. Appropriate trial conduct.

It means that the conduct of the currently noninferiority trial did not undermine its ability to distinguish effective treatments from less effective or ineffective treatments. Appropriateness of trial conduct can only be fully evaluated after the trial is completed. The design should be similar to the historical trials in all aspects as possible (i.e., satisfy the “constancy assumption”), except that the current trial is intended to demonstrate noninferiority of the test treatment to the active control, whereas the historical trials were mostly placebo-controlled trials involving the selected active-control treatment. Most importantly, the trial should be conducted with high quality.

Demonstration of efficacy by showing noninferiority of the test treatment to an active control of proven effectiveness, therefore, rests on a critical assumption that the selected active-control treatment does have a treatment effect in that trial, i.e., with proven historical evidence of sensitivity-to-drug-effects and constancy in effect size. The effect of the active-control treatment has been shown with a minimum size based on historical placebo-controlled trials. That is, if the test treatment had a much smaller effect than that observed in the historical data (or no effect), then the trial would not have concluded noninferior, and in turn, deduced as effective. Even when historical experience indicates that the trials in a particular therapeutic area do support sensitivity-to-drug-effects, it still could be undermined by whether the specific trial actually had assay sensitivity. Because there are many trial-quality-related factors that could reduce the trial assay sensitivity, e.g., poor patient selection, poor drug compliance and excessive dropouts, use of disease-interfering concomitant medications, use of inappropriate or insensitive endpoints, biased assessment of endpoints, inadequate sample sizes and power, and/or vast variability.

Together with historical evidence of sensitivity-to-drug-effects, appropriate trial conduct provides evidence of assay sensitivity in the new trial. A successful active-controlled trial for noninferiority thus involves four critical steps:

1. Determining that historical evidence of sensitivity-to-drug-effects exists. Without this determination, demonstration of efficacy from a showing of noninferiority is not possible and should not even be attempted.
2. Designing a trial to satisfy the constancy assumption. The trial design (e.g., study population, concomitant therapy, endpoints, and run-in periods) needs to adhere closely to the design of the trials for which historical evidence of sensitivity-to-drug-effects has been determined.
3. Setting an appropriate margin. An acceptable noninferiority margin should be chosen, taking into

account the historical data and relevant clinical and statistical considerations.

4. Conducting the trial with high quality. The trial conduct should also adhere closely to that of the historical trials and should be of high quality.

Prior to the trial start, a noninferiority margin, δ , is selected. This margin is the degree of clinical inferiority of the test treatment to the active-control treatment that the trial will attempt to exclude statistically. If the confidence interval for the difference between the test and control treatments excludes the margin, the test treatment can be declared noninferior and thus effective; otherwise, the test treatment cannot be declared noninferior and cannot be considered effective. In this case, “noninferior” means that at least some degree of the efficacy of the active control has been preserved in the test treatment.

Choosing and setting an appropriate margin for an active-controlled noninferiority trials can be difficult. The margin chosen for a noninferiority trial cannot be greater than the smallest effect size that the active-control treatment would be reliably expected based on historical evidence of sensitivity-to-drug-effects. The margin generally is identified based on past experience in placebo-controlled trials of adequate design under conditions similar to those planned for the new trial, but could also be supported by historical positive dose–response or active-controlled superiority trials. The determination of the margin in a noninferiority trial is based on both statistical reasoning and clinical judgment, should reflect uncertainties in the evidence on which the choice is based, and should be suitably conservative.

A major difficulty in the design and conduct of a noninferiority trial is to choose the noninferiority margin appropriately. In many cases, an appropriate margin cannot be chosen because historical evidence of sensitivity-to-drug-effects cannot be supported. Or, the specific trial may not have assay sensitivity (e.g., improper dose/regimen, poor trial conduct, noninferiority expectation, and inadequate statistical power). In either case, a noninferiority trial cannot be properly designed and conducted.

For detailed discussion on active-controlled noninferiority (or equivalence) trials including margin determination, refer to ICH E-10 Guidance,^[1] Hwang and Morikawa,^[3] Hauck and Anderson,^[4] Temple and Ellenberg,^[5] Ellenberg and Temple,^[6] Ng,^[7] Hwang,^[8] and other relevant documents in this encyclopedia.

USEFUL ALTERNATIVES AND DESIGN MODIFICATIONS

Among the five types of controls discussed thus far the most useful ones are the concurrent controls, namely, placebo, active, and dose–response concurrent

controls. Each has ethical or practical limitations, as well as the issues of assay sensitivity and historical evidence of sensitivity-to-drug-effects (active-control noninferiority trials specific) to be satisfied. The following alternatives as suggested^[1,3] are practically useful:

1. Include placebo in addition to the active-control drug (e.g., a three-arm trial) to establish internal assay sensitivity.

It is often possible and advantageous to use more than one kind of control in a single study, e.g., use of both a placebo and an active control. Inclusion of placebo in an active-control trial, for example, a three-arm trial, will add internal evidence of trial assay sensitivity. The three-arm trial with both a known effective active drug and placebo as controls. Such a trial measures the drug effect size (test–placebo difference), and it allows for the comparison of the test and active-control treatments in a setting where assay sensitivity is established by the direct active control–placebo comparison. It is particularly informative even when the test drug and placebo are nondistinguishable in the trial. If the active control is superior to placebo, the trial does have assay sensitivity and will provide evidence that the test drug is not effective. On the other hand, if neither drug, the test, nor the known effective active-control drug can be distinguished from placebo, the trial is proven as not having evidence of assay sensitivity. That is, this three-arm design can readily evaluate whether a failure to distinguish the test drug from placebo is due to ineffectiveness of the test drug, or simply whether a trial does not have assay sensitivity to detect a difference when it exists. Similarly, trials can use several doses of test drug and several doses of an active control, with or without placebo, as previously defined in dose–response concurrent control. This design may be useful for active drug comparisons and establishing relative potency.

2. Show superiority of the test treatment to the low dose of an active-control treatment.

One may design a trial to show superiority of the test treatment to a low dose of a properly selected active-control drug (i.e., “a pseudo” placebo). Using a pseudo-placebo as control, the advantages of placebo control remain, while the ethical concern may be alleviated.

3. Demonstrate a significant dose–response relationship of the test treatment and show difference between doses.

Design a trial to establish a significant dose–response relationship for the test drug and demonstrate pairwise differences between doses (e.g., the highest vs. the lowest) of the test treatment. The dose–response trial is not very useful for dose determination if the trial failed to show any significant

differences between doses. The failure may arise due to a flat dose–response, a narrow therapeutic window, or inadequate statistical power. Again, inclusion of a placebo control (zero dose) will be beneficial.

4. Use the design modifications for placebo control such as the add-on, replacement, early escape, or randomized withdrawal trial, as appropriate.

In many cases, an add-on, replacement, early escape, or randomized withdrawal trial has been shown to be very useful. An add-on trial is a placebo-controlled trial in which the test drug or placebo is added on to a baseline standard treatment via randomization (e.g., in cancer, antiepileptic, and CHF trials). This design is useful only when standard therapy is subeffective, and it has the advantage of providing evidence of improved clinical outcome/response. A variation of this design is the replacement trial, in which the test or placebo is added by random assignment to conventional therapy and then the conventional therapy is withdrawn, usually by tapering. This design has often been used in trials to study steroid-sparing/replacement and antiepileptic drugs. Another design is an early-escape trial, in which therapy of trial patients whose clinical status worsens or fails to improve to a defined level is promptly withdrawn. The need to change therapy will become the primary endpoint in this case. Further modification is a randomized withdrawal trial, in which patients receiving a test drug for a fixed time period are then randomized to continued treatment with the test drug or placebo. The observed difference between the test drug and placebo would demonstrate a treatment effect of the test drug. The postwithdrawal study period can be of fixed duration, use early escape, or time to event.

SELECTION OF CONCURRENT CONTROL

The selection of control can be affected by the availability of treatments and medical practices in specific regions. Assuming that all trials are appropriately designed and carried out, the potential usefulness of the principal concurrent controls (i.e., placebo, active, and dose–response) in specific situations for demonstrating efficacy can be summarized as follows:

- Placebo concurrent control: Show test treatment effects and measure effect size.
- Active concurrent control for superiority: Show test treatment effects and provide comparative efficacy.
- Active concurrent control for noninferiority: May show test treatment effects and provide comparative efficacy pending proven historical evidence of sensitivity-to-drug-effects.

- Dose–response concurrent control: Show test treatment effects and dose–response relationship.
- Multiple concurrent controls (placebo and active): Show test treatment effects, measure effect size, and provide comparative efficacy.
- Multiple concurrent controls (placebo and dose–response): Show test treatment effects, measure effect size, and dose–response relationship.
- Multiple concurrent controls (active and dose–response): Show test treatment effects, dose–response relationship, and may provide comparative efficacy pending proven historical evidence of sensitivity-to-drug-effects.

Based on the above-listed potential usefulness for each type of control, the following basic questions may be asked sequentially to select the proper control(s) for demonstrating test treatment efficacy:

1. Is proven effective (standard) treatment available?
If the answer is “yes,” proceed to the next question. If the answer is “negative,” one must select one of the following (concurrent) controls to show superiority of the test treatment to control with an appropriate design: (1) placebo-controlled with or without design modifications, as appropriate, (2) dose–response-controlled, (3) active-controlled (superiority), or (4) no-treatment controlled with design modifications, as appropriate.
2. Is the proven effective treatment lifesaving and/or known to prevent irreversible morbidity?
If the answer is “negative,” proceed to the next question. If the answer is “yes,” one can select the proven effective treatment as active control to show either superiority or noninferiority (if there is proven historical evidence of sensitivity-to-drug-effects). One may also select the placebo control with appropriate design modifications (e.g., test treatment vs. placebo in an add-on trial).
3. Is there proven historical evidence of sensitivity-to-drug-effects for an appropriately designed and conducted trial?

If the answer is “yes,” one can select any type of control(s) including active control for noninferiority, as appropriate. Otherwise, same as in Question 1 with the “negative” answer, one must select one of the options (i.e., a–d) listed above—it will be infeasible to design and conduct a noninferiority trial.

CONCLUSION

The selection of control is always critical in designing a clinical trial. It affects trial feasibility including ethic consideration, patient recruitment, dose/regimen determination, and endpoint assessment, etc. It also affects many other features of trial design, conduct, and interpretation.

Ultimately, it may affect trial inferences, credibility, and regulatory acceptability.

The utilities of the external/historical controls are rather limited as compared to the concurrent controls (i.e., placebo, active, and dose–response) due to lack of randomization and ability to minimize bias. Each concurrent control with or without modifications has its potential usefulness and limitations. There are also specific issues such as assay sensitivity and historical evidence of sensitivity-to-drug-effects (in particular for active-controlled noninferiority trials), as defined in ICH E-10 Guidance,^[1] need to be well understood.

An appreciation of these critical issues ensures that a proper control is selected for a appropriately designed and conducted clinical trial for demonstrating treatment effectiveness; insurance is given to achieve the trial's intended objectives with scientific and regulatory credibility.

Clinical Trials: Vaccine Development

Ivan S. F. Chan, William W. B. Wang, and Joseph Heyse

Merck Research Laboratories, West Point, Pennsylvania, U.S.A.

Abstract

This entry reviews some of the special considerations in vaccine development, including an increased interest in surrogate markers of activity, a special need for assessing immune responses, and a need for more specificity in endpoint definitions of clinical efficacy based on exposure.

INTRODUCTION

Clinical trials designed to demonstrate the safety and efficacy of new vaccines have a rich history. In 1954, the largest medical experiment in history tested a vaccine to prevent poliomyelitis, one of the most feared childhood diseases. This was the Salk vaccine, named after Dr. Jonas Salk. Close to 2 million children across the United States and Canada participated in this field trial. The vaccine became one of a group of required vaccinations for all children in the United States. Meier^[1,2] discussed the key statistical considerations of that landmark trial. In many ways, the development of clinical trial methods for vaccines has paralleled rather than coincided with the development of trial methods for new drugs and other interventions. Even in the general area of primary prevention research, vaccine trials occupy a distinct place.

Vaccines are biological products that work primarily by introducing antigen or attenuated live virus into the body. Vaccination triggers an immune response in the form of antibodies and T-cell immunity that are specific for the target infectious agent. The presence of antibodies and T-cell immunity plays an important role in limiting the spread of most pathogens and preventing disease infection. Immunologic memory of immune responses enables the body to rapidly produce a large amount of antigen-specific antibodies and T-cells when the infectious agent is detected. The objective of vaccination is to educate the immune system by inducing the immune memory in the absence of the unpleasant clinical features associated with the target infection. Booster doses of vaccines are sometimes administered after several years to ensure that the immune memory is maintained.

Vaccines are used for the prevention of disease and play a critical role in public health policy. Widespread vaccination in a population not only protects vaccinees who are exposed to the infectious agent, but can change the exposure to infection for people who are not vaccinated.

Because vaccines are developed for administration to millions of healthy subjects, often children, there is a premium on safety. A comprehensive evaluation is made to assure that the benefits of vaccination outweigh the risks. Vaccine review at the United States Food and Drug Administration (FDA) is undertaken by the Center for Biologics Evaluation and Research (CBER). The Centers for Disease Control and Prevention (CDC) are also integrally involved in establishing vaccination policy.

OVERVIEW

Clinical trials in vaccine development generally have four phases.^[3,4] Phase I trials are early, small-scale human studies that explore the safety and immunogenicity of multiple dosage levels of a new vaccine. Phase II trials assess the safety, immunogenicity, and, sometimes, efficacy of selected doses of the vaccine, and generate hypotheses for later testing. Phase III trials, usually large in scale, seek to confirm the efficacy of the vaccine in the target population or prove the consistency of manufacturing processes. This is the last stage of clinical studies before licensure of the vaccine is requested. Phase IV trials are often conducted after licensure to collect additional information on the safety, immunogenicity, or efficacy of the vaccine to meet regulatory commitments or postmarketing objectives. Some sponsors further categorize phase IV trials and refer to postmarketing studies as phase V.

This article reviews some of the special considerations in vaccine development, including an increased interest in surrogate markers of activity (often termed as correlates of protection), a special need for assessing immune responses, a need for more specificity in endpoint definitions of clinical efficacy based on exposure, a greater need for confidence in safety, the unique regulatory process, and special health economic considerations of the public health impact of vaccination programs.

REGULATORY PROCESS FOR VACCINE LICENSURE

Vaccines have been successfully developed by using weakened live viruses, inactivated viruses, purified bacterial proteins and glycoproteins, and recombinant, pathogen-derived proteins. In the United States, vaccine development and licensing applications are regulated by the Center for Biologics Evaluation and Research within the Food and Drug Administration. The Center for Biologics Evaluation and Research's mission is to "protect and enhance the public health through regulation of biological and related products including blood, vaccines, and biological therapeutics..."^[5] The manufacture of biological products such as vaccines presents unique regulatory concerns in relation to quality control, consistency, stability, microbial contamination, product administration, and source of the material.^[6] The Center for Biologics Evaluation and Research is responsible for ensuring the safety, purity, and efficacy of biological products intended for use in the treatment, prevention, or cure of diseases or conditions in humans.^[5]

Vaccines are the most common class of biologic products regulated by CBER. The regulatory process starts with a filing of an Investigational New Drug application (IND), when preliminary testing of a new vaccine shows promising results in animals. All clinical trials under an IND are reviewed by CBER. The licensing application for a new vaccine is called the Biologic License Application (BLA), which is similar to the New Drug Application for a drug. When phase I/II studies are near completion and the planning of phase III (pivotal) trials is underway, the sponsor will request a pre-phase III meeting with CBER during the period of late phase II/pre-phase III to discuss a variety of issues, which may include designs of phase III trials, statistical analysis strategies, proposed indications of the vaccine, product profiles, manufacturing process, and facilities. Once phase III trials have been conducted and the sponsor is preparing for the submission of a licensing application, a pre-BLA meeting is usually scheduled with CBER to discuss a variety of topics such as the format and timing of submission, structure of clinical data, and any potential issues that may lead to refusal to file. The last step of applying for vaccine licensure is to file a BLA with CBER. Under the Prescription Drug User Fee Act of 1992, a standard review cycle (12 mo) is assigned for all submissions requiring the review of clinical data that cannot be classified as priority.^[5] The Center for Biologics Evaluation and Research's review of submissions that do not contain clinical data (such as filing of manufacturing changes) are to be completed within 6 mo. During the review of a BLA, CBER may request appropriate FDA advisory committee review of the new vaccine in terms of its efficacy, safety, and public health implications.

The manufacturing process is a fundamental characteristic of the vaccine product. As a result, the description

of chemistry, manufacturing, and controls of the vaccine is particularly important in the licensing application. Because of the inherent variability in the manufacturing process, the concept of a generic drug has not been applied to vaccines. In fact, vaccines made under different manufacturing processes could be considered distinctly different products, although they are indicated for the same disease protection.^[6]

ASSESSING VACCINE EFFICACY

One of the most critical steps of evaluating a new vaccine is to assess the protective efficacy of the vaccine against the target disease. If early phases (phase I/II) of clinical trials have demonstrated that a new vaccine is safe and able to induce immune responses, an efficacy trial (usually phase III, large scale) will often be conducted to evaluate whether the vaccine, as compared with a control, can completely prevent the disease of interest or at least reduce the incidence and/or the severity of the disease in the target population. When the control is a placebo injection or a vaccine that has no effect on the disease, the trial can estimate absolute vaccine efficacy. When the control is an already licensed vaccine for the same disease indication, the trial can estimate relative vaccine efficacy.^[6]

Absolute vaccine efficacy is best assessed in a prospective, randomized, double-blind, placebo-controlled trial in which participants are randomly assigned to receive either a new vaccine (T) or a placebo control (C). Let P_T and P_C represent the true disease incidence rates among N_T vaccinees and N_C controls randomly assigned in the trial, respectively. The vaccine efficacy, denoted by π , measures the relative reduction of the disease incidence in the vaccine group compared with the placebo group. A widely used measure of vaccine efficacy (π) is given by

$$\pi = 1 - R, \quad \text{where } R = P_T/P_C \quad (1)$$

Here R represents the relative risk of contracting the disease between the vaccine and placebo groups. In general, it is assumed that a new vaccine candidate will not be worse than placebo ($P_T \leq P_C$). A vaccine is 100% efficacious ($\pi = 1$) if it prevents the disease completely ($P_T = 0$), and it has no efficacy ($\pi = 0$) if $P_T = P_C$. Technically, however, the efficacy π can be negative if the vaccine group has a higher disease incidence rate than the placebo group.

In designing a vaccine efficacy trial, one needs to ensure that the study has sufficiently high power to test the hypothesis

$$H_0 : \pi \leq \pi_0 \text{ versus } H_1 : \pi > \pi_0 \quad (2)$$

where π_0 denotes the minimal level of efficacy considered to be acceptable for the new vaccine. This is equivalent to requiring a high level of confidence that the vaccine

efficacy is greater than the prespecified lower bound (π_0). While π_0 could be 0, as is typically the case in establishing therapeutic efficacy of a new drug, considering a lower bound of 0 in vaccine trials involving healthy participants is usually not sufficient. In fact, it is a regulatory requirement to demonstrate that the protective efficacy of a new vaccine is significantly greater than some nonzero lower bound ($\pi_0 > 0$); this requirement was established so that researchers define more precisely the benefit of the vaccine and justify the risk of vaccinating potentially millions of healthy individuals.^[7] This nonzero lower bound is often called a “super efficacy” requirement. Orenstein, Bernier, and Hinman^[8] gave an excellent review of the design considerations for vaccine efficacy evaluation in terms of case definition, case finding, vaccination status ascertainment, and assuring comparability of vaccinated and unvaccinated groups. Lachenbruch^[9] discussed how the specificity and sensitivity of the case definition affects the vaccine efficacy estimate and concluded that a less-specific case definition will lead to a severe underestimation of the vaccine efficacy. Ellenberg and Dixon^[10] and Rida and Lawrence^[11] discussed many important statistical issues related to HIV vaccine trials.

Vaccine Efficacy Based on the Ratio of Two Binomial Proportions

In a randomized vaccine efficacy trial, the number of disease cases in the vaccine and control groups can be assumed to follow independent binomial distributions with parameters (N_T, P_T) and (N_C, P_C), respectively. This assumption is practical if the trial has a relatively short duration or all participants are completely followed through the end of the trial. If so, then a natural estimate of vaccine efficacy is

$$\hat{\pi} = 1 - \hat{R}, \quad \text{where } \hat{R} = \hat{P}_T / \hat{P}_C \quad (3)$$

Here $\hat{P}_T$ and $\hat{P}_C$ are the observed proportions of participants in the vaccine and control groups, respectively, who develop disease during the trial.

In this case, asymptotic methods for analyzing vaccine efficacy (hypothesis test and confidence interval) are direct applications of methods for estimating the relative risk of two binomial proportions; these methods have been extensively discussed in the literature.^[12–18] Of common use is the Z-type method proposed by Miettinen and Nurminen.^[7,13,16]

$$Z_E = \frac{\hat{P}_T - (1 - \pi_0)\hat{P}_C}{\hat{\sigma}_0 / \sqrt{N_T}} \quad (4)$$

where

$$\hat{\sigma}_0 = \left[\tilde{P}_T(1 - \tilde{P}_T) + \frac{1}{u}(1 - \pi_0)^2 \tilde{P}_C(1 - \tilde{P}_C) \right]^{1/2}, \quad u = N_C / N_T \quad (5)$$

and ($\tilde{P}_T, \tilde{P}_C$) are the constrained maximum likelihood estimates of (P_T, P_C) under the null hypothesis given in Eq. (2) based on the observed responses ($\hat{P}_T, \hat{P}_C$). Detailed expressions of (T, C) are given in Refs. [7,13]. The vaccine efficacy is demonstrated (rejecting the H_0) at the one-sided α (usually 2.5%) significance level if $Z_E \leq -Z_\alpha$, where Z_α is the 100(1 - α) percentile of the standard normal distribution. This Z_E test is equivalent to the likelihood score test^[16] and performs very well in many practical applications.^[7,13,16] In addition to hypothesis testing, this method provides a test-based confidence interval that ensures consistent inference with the corresponding p -value. Asymptotic formulas for sample size and power calculations for vaccine efficacy (or relative risk) studies can be found in reports by O'Neill,^[19] Farrington and Manning,^[15] Blackwelder,^[16] and Nam.^[18] Exact inference of vaccine efficacy has been proposed by Chan^[20] and discussed by Chan and Bohidar^[7] in terms of power and sample size calculation. An example of sample size and power calculation based on the Z_E test is given in “Sample Size and Power Calculation for Vaccine Efficacy Trials.”

Vaccine Efficacy Based on the Ratio of Two Rates

When the disease incidence rate is very low, a large-scale study is usually required to demonstrate vaccine efficacy. For sufficiently large sample sizes and small incidence of disease, the numbers of cases in the vaccine and placebo groups may be approximated by independent Poisson distributions with rate parameters λ_T ($\approx N_T P_T$) and λ_C ($\approx N_C P_C$), respectively. In this case, the number of cases in the vaccine group, given the total number of cases (S), is distributed as binomial (S, θ) where

$$\theta = \frac{\lambda_T}{\lambda_T + \lambda_C} = \frac{N_T P_T}{N_T P_T + N_C P_C} = \frac{R}{R + u} = \frac{1 - \pi}{1 - \pi + u} \quad (6)$$

where $u = N_C / N_T$

Because θ is decreasing in π , the efficacy hypothesis in Eq. (2) is equivalent to

$$H_0 : \theta \geq \theta_0 \text{ versus } H_1 : \theta < \theta_0 \quad (7)$$

where $\theta_0 = (1 - \pi_0)/(1 - \pi_0 + u)$. Blackwelder^[16] discussed many asymptotic methods for constructing hypothesis tests and interval estimation regarding vaccine efficacy. For testing the classical null hypothesis with $\theta_0 = 0$, an exact conditional inference based on the Clopper and Pearson method^[21] has been proposed.^[22,23] Chan and Bohidar^[7] discussed a generalization of this exact conditional method for testing efficacy hypotheses with nonzero lower bounds. They found that the exact conditional test works extremely well for low incidence rates. This exact conditional method has been used to analyze the efficacy of vaccines for the prevention of hepatitis A,^[24] herpes zoster, and cervical cancer.

This exact conditional method^[7] can also be used to design a study whose goal is to accrue a fixed number of events instead of running for a fixed duration. Once the total number of events is fixed, the power of the study depends on incidence rates only through the true efficacy, not the disease incidence rate. Thus one can avoid a situation sometimes encountered in a fixed-duration trial in which the anticipated power was not achieved at the end of the trial because the unexpectedly low incidence rates resulted in too few events.^[7] In addition, the Poisson assumption also allows the exact conditional method to handle person-time data easily. This flexibility is important in long-term studies, in which follow-up often differs between the treatment groups. Sample size and power calculation based on this exact conditional method are discussed in Chan and Bohidar,^[7] and an example is given in “Sample Size and Power Calculation for Vaccine Efficacy Trials.”

In longitudinal vaccine efficacy trials, time-to-event type analyses such as the Cox proportional hazards model^[25] may also be used to compare the disease outcomes between the treatment groups. In this case, the vaccine efficacy may be estimated as the ratio of the hazard rates between vaccine and placebo groups.

Trials to Estimate Relative Vaccine Efficacy

When the control is an already licensed vaccine, a randomized efficacy trial can estimate the relative efficacy (π) of a new vaccine via the relative risk ($R = P_T/P_C$) based on the relationship $\pi = 1 - R$. If the absolute efficacy of the control (π_C) has been established, one can estimate the absolute efficacy of the new vaccine (π_T) through the indirect argument^[26,27]

$$\pi_T = 1 - R(1 - \pi_C) \quad (8)$$

A trial to compare the relative efficacy focuses on the relative risk (R). It is usually designed as a noninferiority trial and tests the hypothesis

$$H_0 : R \geq R_0 \text{ versus } H_1 : R < R_0 \quad (9)$$

where R_0 (> 1) is a prespecified noninferiority margin or relative risk threshold. The trial is powered to show that the relative risk R is less than R_0 such that the lower bound of the confidence interval for the estimated absolute vaccine efficacy (π_T) is greater than $(1 - R_0(1 - \pi_C))$ with a high likelihood.^[26] The choice of the noninferiority margin should be based on clinical, regulatory, and statistical judgments so that ruling out a relative risk of R_0 or larger between the new and control vaccines will imply that the new vaccine preserves a large proportion of the efficacy of the control vaccine. Although a noninferiority margin that preserves 50% of the treatment effect has been proposed for the evaluation of drug treatments,^[28–30] there is a general perception that a narrower margin should be used in

preventive vaccine trials because the vaccine will be given to healthy individuals for prophylaxis.

Other Considerations for Vaccine Efficacy Estimates

The vaccine efficacy estimates discussed in previous sections measure the direct effect of the vaccine on the prevention of the disease infection (reduction of disease incidence). Sometimes a vaccine may reduce both the incidence and the severity of the target disease. For example, the chickenpox vaccine has been shown to be more than 90% efficacious in preventing chickenpox in children 1 to 12 yr of age.^[31–33] Furthermore, in vaccinated children who developed chickenpox, the severity (number of lesions and fever) was generally much milder than in unvaccinated children who contracted chickenpox.^[33] Chang, Guess, and Heyse^[34] proposed a combined measure of efficacy, which considers both incidence and severity in evaluating the total direct effect of a vaccine. Recent clinical trials have used this composite efficacy measure, called burden-of-illness, to evaluate the efficacy of new vaccines for the prevention of rotavirus diarrhea in children and herpes zoster in elderly persons. The burden-of-illness approach has also been adapted to compare injection-site symptoms of two hepatitis A vaccines.^[35]

Besides the direct benefits, vaccination also often produces indirect benefits to unvaccinated persons by reducing person-to-person transmission of the disease in the population. Examples of vaccines conferring indirect benefits include the oral polio vaccine, the *Haemophilus influenzae* type B vaccine, and the measles–mumps–rubella vaccine. This indirect effect of the vaccine is called herd immunity.^[36] Extensive work has focused on design and analysis in vaccine trials to estimate the indirect effect and the vaccine efficacy for the reduction of disease transmission rate or secondary attack rate.^[4,37–40] This vaccine efficacy on disease transmission rate is an important measure for evaluating new vaccines intended to prevent diseases with cluster exposures, such as HIV infection.

Investigation of waning (or long-term) vaccine efficacy is also an important issue in vaccine trials. If long-term follow-up data on persons who received vaccines and those who received placebo are available, one can divide the study duration into different time intervals, estimate vaccine efficacy for each interval, and then examine the estimates for trends.^[4] Durham et al.^[41] used a nonparametric survival method to estimate the long-term efficacy of a cholera vaccine in the presence of waning protection. In many instances, long-term follow-up data on placebo controls are not available because these participants would have been offered vaccination once the vaccine has been shown to be efficacious. In such cases, long-term disease breakthrough rates among vaccinees can be compared with age-specific rates from the unvaccinated susceptible population to evaluate the long-term vaccine efficacy.^[33]

Time-to-event analyses can also be performed to examine whether breakthrough rates among vaccinees change over time. However, assessing waning vaccine efficacy without concurrent controls may be subject to bias because the disease epidemiology may change over time, particularly with the increased vaccination coverage after licensure of the vaccine.

Sample Size and Power Calculation for Vaccine Efficacy Trials

As discussed in “Vaccine Efficacy Based on the Ratio of Two Binomial Proportions” and “Vaccine Efficacy Based on the Ratio of Two Rates,” there are many methods of calculating sample size and power for vaccine efficacy trials. Here we briefly describe the methods based on the commonly used asymptotic Z_E test and the exact conditional test in a placebo control trial setting. For testing the null hypothesis $H_0: \pi \leq \pi_0$ against a specific alternative $H_1: \pi = \pi_1$ ($\pi_1 > \pi_0$), the asymptotic power of an α level Z_E test is given by

$$1 - \beta = \Phi \left\{ \frac{1}{\sigma_1} \left[-Z_\alpha \bar{\sigma}_0 + \sqrt{N_T} P_C (\pi_1 - \pi_0) \right] \right\} \quad (10)$$

where σ_1 is the value of the expression in Eq. (5) when $\tilde{P}_T$ and $\tilde{P}_C$ are replaced with P_T and P_C , respectively, $\bar{\sigma}_0$ is the limiting value of $\tilde{\sigma}_0$ in Eq. (5) obtained by calculating $(\tilde{P}_T, \tilde{P}_C)$ at the point $(\tilde{P}_T, \tilde{P}_C) = (P_T, P_C)$, and Φ is the standard normal distribution function.^[7] Similarly, the asymptotic sample size for an α level Z_E test with $(1 - \beta)$ power is given by

$$N_T = (Z_\alpha \bar{\sigma}_0 + Z_\beta \sigma_1)^2 / [P_C (\pi_1 - \pi_0)]^2 \quad (11)$$

and $N_C = u N_T$

For example, suppose we design a study to test the efficacy hypothesis with a lower bound of π_0 of 0.2 at the one-sided 2.5% level, and we would like to achieve 95% power if the true vaccine efficacy is 0.8. Assuming equal sample sizes and a disease incidence rate of 0.6% in the placebo control group, the total number of subjects needed for the study will be approximately 10,838 based on Eq. (11).

To calculate the power using the exact conditional method, we first compute the critical value Y_C corresponding to the one-sided α level test. Given a total number of cases (T) desired for the study and $\theta_0 = (1 - \pi_0)/(1 - \pi_0 + u)$ under the null hypothesis, Y_C can be determined as the maximum number of cases in the vaccine group such that the null hypothesis is rejected: $\Pr[Y \leq Y_C | Y \sim \text{Binomial}(T, \theta_0), H_0] \leq \alpha$. Then the power is given by Chan and Bohidar^[7] as

$$1 - \beta = \Pr[Y \leq Y_C | Y \sim \text{Binomial}(T, \theta_1), H_1] \\ = \sum_{k=0}^{Y_C} \theta_1^k (1 - \theta_1)^{T-k} \quad (12)$$

where $\theta_1 = (1 - \pi_1)/(1 - \pi_1 + u)$. One can also use Eq. (12) to iteratively determine the total number of cases (T) required for the study to achieve the desired power. Because the unconditional expected value of T is $(N_T P_T + N_C P_C)$, we can estimate the number of participants needed for the study as

$$N_T = T / [(1 - \pi_1 + u) P_C] \text{ and } N_C = u N_T \quad (13)$$

For the above example, a total number of cases of 37 will ensure the study to have at least 95% power to show the vaccine efficacy. Based on the disease incidence rate of 0.6% in the placebo control group, the total number of subjects required for enrollment is estimated to be 10,278 using Eq. (13), which compares favorably with the sample size of 10,838 obtained based on the asymptotic formula.

ASSESSING VACCINE IMMUNOGENICITY

Vaccine immunogenicity clinical trials study the immune response to vaccination, which are usually measured by serum antibody titers or T-cell responses. Many immunogenicity trials are conducted in the early phases of vaccine development to assess whether the vaccine can induce immunity before large-scale efficacy trials are performed. In addition, immunogenicity of a vaccine is typically assessed in an efficacy trial to determine whether an immune marker to the vaccine can be used as a surrogate or correlate of disease protection (see the section “Immune Surrogate and Correlate of Protection for Vaccines” for more details).

Once an immune surrogate or correlate of protection has been established, immunogenicity trials can be used as efficient alternatives (for time and economical considerations) to efficacy trials in evaluating the effectiveness of future vaccines. After the successful demonstration of vaccine efficacy, for example, immunogenicity trials are typically used to demonstrate the consistency of vaccine manufacturing process; to prove the vaccine effectiveness when manufacturing processes, storage conditions, or vaccination schedules are modified; to justify concomitant use with other vaccines; and to develop a new combination vaccine with multiple components. The primary objective of such immunogenicity studies is to demonstrate that a new (or modified) vaccine is noninferior (or equivalent) to the current vaccine by ruling out a prespecified clinically relevant difference in the immune response.

General Approaches to Immunogenicity Analysis

Immunogenicity Endpoints

Two types of immunologic endpoints are commonly used to assess vaccine immunogenicity: (1) an immune

response rate, defined as the percentage of participants who achieve a certain level of immune response after vaccination (yes/no); and (2) a geometric mean titer (GMT) or geometric mean concentration of immune response after vaccination. When a particular level of immune response has been shown to be correlated with disease protection, the percentage of participants achieving the “protective level” after vaccination is usually considered the primary endpoint for immunogenicity analyses. In studying participants with preexisting immunity, additional endpoints may include the percentage of participants who develop a certain (e.g., fourfold) fold-rise and the geometric mean fold-rise in immune response from before to after vaccination.

Approaches for Analyzing Immune Response Rates

For the analyses of immune response rates, we consider the general setting comparing a new vaccine (T) to a control (C) in a randomized study. If the control is a placebo, the study is designed as a superiority trial. If the control is a licensed vaccine, the study is often designed as a noninferiority trial. Using the notation of “Assessing Vaccine Efficacy,” let P_C and P_T represent the true immune response rates of the control (with N_C subjects) and the new vaccine group (with N_T subjects), respectively. Then the number of successes (i.e., participants who achieve a certain level of immune response) in the control and new vaccine groups is independently distributed as binomial (N_C, P_C) and binomial (N_T, P_T), respectively. In general, the study can be designed to test the statistical hypothesis (superiority or noninferiority)

$$H_0: P_T - P_C \leq -\delta \text{ versus } H_1: P_T - P_C > -\delta \quad (14)$$

where δ is a prespecified small quantity defining the noninferiority margin. The nominal significance level for the one-sided test is generally set at half of the conventional significance level for a two-sided test for the difference in proportions. This approach has been adopted in regulatory environments, as suggested in the International Conference on Harmonization E9 (ICH E9) guidelines.^[42]

When $\delta = 0$, the hypothesis (Eq. [14]) reduces to the classical one-sided hypothesis aimed to show that the new vaccine is superior to the control. Standard asymptotic methods for testing a null hypothesis of no difference in two proportions can be used.^[43] In addition, exact methods are available for testing this hypothesis^[44,45] and for constructing confidence intervals.^[46,47] Finally, some discussions and debates of one-sided versus two-sided hypothesis for superiority testing can be found in Peace^[48] and Fisher.^[49]

When δ is a small positive quantity, the hypothesis above (Eq. [14]) aims to show that the new vaccine is noninferior (or equivalent) to the control vaccine. Considerations for the choice of noninferiority margin δ are discussed below at the end of “General Approaches to Immunogenicity Analysis.” Asymptotic statistical tests of the noninferiority

hypothesis (Eq. [14]) for two independent treatment groups with a dichotomous endpoint have been extensively discussed in the literature (e.g., Refs. [13,15,50–52]). Many authors have proposed Z-type test statistic with different standard error estimates.^[13,51,52] Of common use and better performance is the Z-type method proposed by Miettinen and Nurminen:^[13,15]

$$Z_D = \frac{\hat{P}_T - \hat{P}_C + \delta}{\tilde{\sigma}_{02} / \sqrt{N_T}} \quad (15)$$

where

$$\tilde{\sigma}_{02} = \left[\tilde{P}_T(1 - \tilde{P}_T) + \frac{1}{u} \tilde{P}_C(1 - \tilde{P}_C) \right]^{1/2}, \quad (16)$$

$$u = N_C / N_T$$

and $(\tilde{P}_T, \tilde{P}_C)$ are the constrained maximum likelihood estimates of (P_T, P_C) under the null hypothesis given in Eq. (14) based on the observed responses $(\hat{P}_T, \hat{P}_C)$. Detailed expressions of $(\tilde{P}_T, \tilde{P}_C)$ are given in Refs.^[13,15] The noninferiority is established (H_0 rejected) at the one-sided α significance level if $Z_D \geq Z_\alpha$, where Z_α is the 100(1 - α) percentile of the standard normal distribution. For immunogenicity trials with small sample sizes, as are often conducted in the early phases of vaccine development, exact tests and confidence intervals^[20,46,53] can be used to compare treatments and test the hypothesis in Eq. (14).

Some immunogenicity trials also involve a hypothesis regarding whether the new vaccine induces an adequate immune response compared with a historical control.^[54] The statistical hypothesis of interest is that $H_0: P_T \leq p_0$ versus $H_1: P_T > p_0$, where p_0 is the prespecified lower limit determined from the historical control data. The statistical criterion for this hypothesis is equivalent to requiring that the lower bound of the confidence interval on the single group immune response is larger than the prespecified lower limit. A confidence interval for immune response rate can be computed by using asymptotic or exact methods for a single binomial proportion.

Approaches for Analyzing Geometric Mean Titers

For the comparison of GMTs, an immunogenicity study is usually designed to test the following general statistical hypothesis:

$$H_0: \text{GMT}_T / \text{GMT}_C \leq K \text{ versus } H_1: \text{GMT}_T / \text{GMT}_C > K \quad (17)$$

where GMT_C and GMT_T represent the GMTs of the control and new vaccine groups, respectively, and K is a prespecified positive quantity relevant to the comparison of fold-difference between the two GMTs. Titers are usually log-transformed in the statistical analysis. The confidence interval for individual GMTs is often calculated on the basis of the asymptotic t -distribution.

When $K = 1$, the hypothesis (Eq. [17]) reduces to the classic one-sided hypothesis of superiority of the new vaccine compared with the control. When $0 < K < 1$, the rejection of the null hypothesis H_0 in 17 at a prespecified α level (usually one-sided $\alpha = 0.025$) leads to the conclusion that the new vaccine is noninferior to the control with respect to the GMTs, with an interpretation that a difference in GMTs (control/new) is $< 1/K$ -fold. This statistical criterion corresponds to the lower bound of the corresponding two-sided $(1 - 2\alpha)$ 100% confidence interval on the ratio of GMTs being greater than K . Some considerations for the choice of noninferiority margin K are given next. The statistical testing and confidence interval estimation regarding GMTs can be performed by using an analysis of variance (ANOVA), an analysis of covariance, or a linear mixed-effects model that includes natural log of the antibody titer as the dependent variable and uses treatment group, baseline, and stratification variables as explanatory variables.

In addition to these parametric analyses on GMTs, graphical displays of reverse cumulative distribution curves of $\Pr(X \geq x)$,^[55] which give percentages of participants with titers greater than or equal to varying levels of titers (x), are commonly used for exploratory evaluation of immune response to vaccination. Nonparametric methods have also been proposed to estimate the overlap or the proportion of similar response in distributions, which can be used to measure the similarity between two distributions of immune response.^[56]

Considerations for Noninferiority/Equivalence Margins

In general, the choice of δ and γ , called noninferiority or equivalence margins, depends on the level of correlation between immune responses and the vaccine efficacy, the variability of immunogenicity measures, and the importance of these endpoints in the trial. The choice should be based on statistical reasoning as well as on clinical and regulatory judgments so that ruling out a difference of δ in immune response rates (or a fold-difference of $1/K$ in GMTs) between the new vaccine and the control will demonstrate that the effectiveness of the new vaccine is comparable to that of the control. For example, in studies of the hepatitis A vaccine VAQTA®, a Δ of 10 percentage points is typically used as the noninferiority margin for comparing immune response rates, which are usually greater than 90%.^[57] A K of 0.67, 0.5, or 0.25 (corresponding to 1.5-, 2-, or 4-fold difference) are often used in comparing GMTs. These noninferiority margins should be discussed proactively between the sponsor and regulatory agencies. Regulatory agencies usually apply the same requirements of equivalence margins for the same endpoints when reviewing similar products from different companies. More general discussions on the choice of noninferiority or equivalence margins can be found in Temple,^[28] Jones et al.,^[29]

Ebbutt and Frith,^[30] the ICH E9 guidelines,^[42] the ICH E10 guidelines,^[58] Siegel,^[59] and Wiens.^[60]

Different Types of Vaccine Immunogenicity Studies

Superiority Immunogenicity Study

Immunogenicity studies are often conducted in the early phases of vaccine development to assess vaccine immunogenicity compared with a placebo. In addition, immunogenicity trials can also be performed to claim superiority of one vaccine over another vaccine from a different manufacturer with respect to immune responses. Such immunogenicity trials should be designed as a superiority (difference-detection) trial rather than an equivalence or noninferiority trial. In this case, the conventional null hypothesis of no difference should be tested against a one-sided alternative or two-sided alternative. The analysis strategy follows the methods for $\Delta = 0$ or $K = 1$ described in the section “General Approaches to Immunogenicity Analysis.”

Dose Response Immunogenicity Study

During vaccine development, a dose–response study may be conducted to assess the immunologic response across different dosage levels of the vaccine and thus determine the minimum effective and safe dose. For many live-virus vaccines, the potency of the vaccine may decay over time. A dose–response study will help investigators understand the kinetic of potency decay, determine the release and end-expiry dosage level, and specify the shelf life of the vaccine. Immune response rates and GMTs are often co-primary endpoints in this type of study. The existence of a dose–response trend in the immune response rate can be tested by using the Cochran–Armitage (C–A) trend test.^[61,62] A dose–response trend with respect to GMTs can be evaluated by using an ANOVA model. Multiple testing procedures^[63,64] can be used to control the overall type I error rate if multiple trend tests or comparisons are made.

Consistency Lots Study

Vaccines are biological products, and their manufacturing process generally varies much more widely than does that of chemical drug products. Before a vaccine can be licensed, the sponsor must demonstrate consistency of the vaccine manufacturing process through analytical and clinical testing. A clinical consistency lot study typically uses three lots of vaccines made from the same manufacturing process (called consistency lots) and a control vaccine (see an example in Ref. [57]), and is intended to (1) rule out a clinically significant difference in either direction between any two pairs of the three consistency lots; and (2) rule out a clinically significant difference

between the combined immune response of three consistency lots and the response of the control. A consistency lot study is typically designed as a two-sided equivalence study with respect to both an immune response rate and a GMT.

The hypothesis of consistency among three lots of vaccine with respect to immune response rate can be written as

$$\begin{aligned} H_0: |P_i - P_j| \geq \Lambda \text{ for at least one pair } (i, j) \\ \text{versus } H_1: |P_i - P_j| < \Lambda \text{ for every } (i, j) \text{ pair} \end{aligned} \quad (18)$$

where P_i and P_j are the immune response rates for lots i and j , $1 \leq i < j \leq 3$. Testing this hypothesis is equivalent to testing three pairs of noninferiority hypothesis tests,^[65] all of which must be rejected for consistency to be declared among the three lots. The nominal level of significance for the consistency lots hypothesis is usually set at the $\alpha = 0.05$ level, at which all six hypotheses are tested. The statistical criterion is equivalent to requiring that all two-sided 90% confidence intervals for the three pairwise differences in immune response rates fall within the interval of $(-\delta, \delta)$. The analysis approach for each noninferiority hypothesis can follow the methods described in “General Approaches to Immunogenicity Analysis.” Wiens and Iglewicz^[66] proposed a slightly improved statistic to test the hypothesis (Eq. [18]). Once the consistency among the three vaccine lots has been demonstrated, the immune response for the three lots can be pooled and compared with the response of the control in a noninferiority hypothesis setting. The hypothesis testing strategy for clinical lot consistency with respect to GMTs can be structured in a fashion similar to that for the immune response rate. The sample size and power for consistency lot studies can be calculated by using simulation.^[65] More discussions on sample size and power calculations can be found in the section “Sample Size and Power Considerations for Vaccine Immunogenicity Studies.”

Bridging Study

After vaccine licensure, manufacturing processes, storage conditions, routes of administration, or dosing schedules may be changed to improve production yields, potency stability, or convenience of vaccination schedule. It is a regulatory requirement to conduct a bridging study (comparing a modified vaccine with the current vaccine) to demonstrate that such changes do not have adverse effects on vaccine effectiveness. If an immune marker correlates with disease protection (see “Immune Surrogate and Correlate of Protection for Vaccines” for more details), immunogenicity bridging trials can be conducted instead of efficacy trials to show clinical equivalence or noninferiority of the modified vaccine to the current vaccine.

An immunogenicity bridging trial is commonly designed as a noninferiority trial aimed at excluding a clinically significant difference in the immune response between the modified vaccine and the current vaccine. The analysis strategy usually follows the methods described in “General Approaches to Immunogenicity Analysis.” The noninferiority hypothesis is usually tested at $\alpha = 0.025$. The key for determining the study hypothesis is the choice of the noninferiority margin, namely, a clinically tolerable difference in proportions (Λ) or fold-difference in GMTs (K) between the modified vaccine and the current vaccine. As discussed in “General Approaches to Immunogenicity Analysis,” the choice of Λ and K depends on the level of correlation between immune responses and the vaccine efficacy, the variability of immunogenicity measures, and the importance of these endpoints.

Combination or Multivalent Vaccine Study

A combination or multivalent vaccine consists of two or more live organisms, inactivated organisms or purified antigens combined by the manufacturer or mixed immediately before administration. The vaccine is intended to prevent multiple diseases, prevent one disease caused by different strains or serotypes of the same organism, or reduce the number of injections and health care visits.^[67] The immunogenicity of all the vaccine components in the combination or multivalent vaccine should be studied to rule out the clinically significant differences in immune response rates or GMTs between the combined vaccine and the separate but simultaneously administered antigens.^[57,67,68] In addition, acceptable levels of immunogenicity should be demonstrated for each serotype or component.^[67,69] In most cases, the endpoints for each component are considered co-primary, and the success requires the demonstration of similarity for all components (see case 2 in Ref. [70]). In some cases, the success requires the demonstration of similarity for any M of the K components (see case 3 in Ref. [70]). For this kind of problems, Capizzi and Zhang^[70] and Ruger^[71] discussed multiplicity adjustments using the ordered test statistics for individual endpoints or using “hybrid” decision rules.

Immunologic Persistence Study

The clinical development phase of a vaccine often takes several years before reaching its licensure. However, the duration of vaccine-induced immunity is expected to be considerably longer than the duration of the clinical studies. Thus there are both conceptual and methodological challenges in assessing whether immunity is waning and in estimating long-term immunologic persistence (defined as the presence of vaccine-induced antibody or cell-mediated immunity over time). To this end, immunologic studies (often open-labeled) are conducted, even after vaccine licensure, to annually measure the immune responses over

multiple years. Life-table or time-to-event analyses^[72] can be used to analyze the cumulative immunologic persistence rate.^[33] In addition, several modeling strategies have been proposed to predict the duration of vaccine-induced immunity based on the extrapolation of observed antibody data from the clinical studies.^[73–75] Although prediction from these extrapolation models relies on many assumptions, they may be useful for developing vaccine booster recommendation and epidemiologic surveillance.^[75]

Sample Size and Power Considerations for Vaccine Immunogenicity Studies

Sample size and power calculation for vaccine immunogenicity trials usually follow the same principles and formula as in the drug trials. Appropriate sample size and power estimations for immunogenicity studies depend on (1) reasonable assessments of source and magnitude of immunologic variability; (2) meaningful determinations of clinically significant difference/threshold in immune response rates or geometric mean titers; (3) clearly stated study hypotheses and endpoints; and (4) well-planned statistical analysis strategies.

Bridging Study

For bridging studies that are designed to test the noninferiority hypothesis (Eq. [14]) with respect to immune response rates, there are many methods of calculating the sample size and power. Of common use is the sample size formula proposed by Farrington and Manning,^[15] which is based on the Z -type test statistic (Eq. [15]). To have a $1 - \beta$ power to claim noninferiority at one-sided α level, the approximate sample size for testing the hypothesis (Eq. [14]) should be

$$N_T = \{Z_\alpha \bar{\sigma}_{02} + Z_\beta \sigma_{12}\}^2 / (P_T - P_C + \delta)^2 \quad (19)$$

and $N_C = uN_T$

where u is the prespecified sample size ratio between the control and the test vaccine groups, P_C and P_T are the expected immune response rates for control and test vaccine groups in the planned study, respectively, Z_φ is the $100(1 - \varphi)$ percentile of the standard normal distribution, σ_{12} is the value of the expression in 16 when the constrained maximum likelihood estimates $\hat{P}_T$ and $\hat{P}_C$ are replaced with P_T and P_C , respectively, and $\bar{\sigma}_{02}$ is the limiting value of $\hat{\sigma}_{02}$ in Eq. (16) obtained when $(\hat{P}_T, \hat{P}_C)$ are calculated taking $(\hat{P}_T, \hat{P}_C) = (P_T, P_C)$. Similarly, the asymptotic power of a one-sided α level Z_D test is given by

$$1 - \beta = \Phi \left\{ \frac{1}{\sigma_{12}} \left[-Z_\alpha \bar{\sigma}_{02} + \sqrt{N_T} (P_T - P_C + \delta) \right] \right\} \quad (20)$$

where Φ is the standard normal distribution function.

To illustrate the sample size calculation under this setting, let us assume that one needs to design a bridging study to rule out a 10 percentage-point difference in immune response rate between a new test vaccine and a control vaccine. The noninferiority margin in the study hypothesis (Eq. [14]) is 10% (i.e., $\Lambda = 0.1$). Assuming the hypothesis is tested at one-sided $\alpha = 0.025$ level and the expected immune response rates for both groups are 90% in the planned study (i.e., $P_C = P_T = 0.9$), then in order to have 95% power to rule out a 10 percentage-point difference between the equally sized test and control groups, ~250 subjects per group are required to be evaluable for the primary analysis. Assuming a 10% nonevaluable rate because of protocol violation, loss to follow-up, invalid assay results, etc., ~280 subjects should be enrolled in each group.

For bridging studies that are designed to test the noninferiority hypothesis in Eq. (17) with respect to the GMTs, the sample size calculation is similar to that for testing the conventional hypothesis of no difference under the lognormal assumption. Let l be the standard deviation of the log-transformed antibody titer. In order to achieve $1 - \beta$ power in testing the hypothesis (Eq. [17]) at the one-sided α level, the sample size for the test vaccine group is:

$$N_T = (1 + 1/u)(Z_\alpha + Z_\beta)^2 \sigma^2 / [\log(R_{\text{GMT}}) - \log(\gamma)]^2 \quad (21)$$

and $N_C = uN_T$

where u is the prespecified sample size ratio between the control and the test vaccine groups and R_{GMT} ($\text{GMT}_T / \text{GMT}_C$) represents the ratio of GMTs between the new and control vaccine groups under the alternative hypothesis. Similarly, the asymptotic power of a one-sided α level test based on the normal approximation is given by

$$1 - \beta = \Phi \left\{ Z_\alpha + \frac{1}{\sigma} \sqrt{\frac{N_T}{(1 + 1/u)}} [\log(R_{\text{GMT}}) - \log(\gamma)] \right\} \quad (22)$$

Consistency Lot Study

When planning a consistency lot study to compare three clinical lots, no closed-form formula exists for sample size calculation, and simulation study can be used to adequately plan the sample size.^[65] For power estimation, Wiens, Heyse, and Matthews recommended performing simulations with the three population parameters under the alternative hypothesis of being not all equal. For example, for hypothesis testings with respect to the immune response rate, they recommended performing simulations under the setup that the true immune response rates for the three groups are P_1 , P_1 , and $P_1 + 0.5\Lambda$, instead of being all equal. This gives a conservative estimate of power when the alternative hypothesis is true.^[65]

Combination or Multivalent Vaccine Study

In a combination or multivalent vaccine study, the hypotheses regarding each component or each serotype are often considered as co-primary. In planning such a study, sample size for each primary hypothesis can be calculated using formulas 19, 21, or other related sample size formulas for that hypothesis. To address the concerns of multiplicity, one approach is to plan the power for each primary hypothesis large enough such that the overall power is acceptable under the assumption of independence among the multiple hypotheses. This approach is generally conservative (estimating lower bound of power) because the correlation between components is usually positive. For example, for a multivalent vaccine with k components, one can plan the power for hypothesis testing on each component to be at least $1 - \beta/k$ so that the overall power is guaranteed to be no less than $1 - \beta$.

ASSESSING VACCINE SAFETY

A complete evaluation of safety is an important component in all vaccine development programs. The safety considerations of vaccines differ from those of the pharmaceutical products because of the fundamental role of vaccines in public health initiatives. Vaccines are administered to millions of healthy individuals around the world with the objective of preventing infectious diseases. Many vaccines are mandated for entry into public schools, day care and preschool programs, and even universities. Safety evaluations begin with the earliest preclinical experiments and continue throughout the clinical development program and marketing life span of the vaccine. Phase IV postlicensure regulatory commitments typically include a formal safety evaluation in a large managed health care setting. In addition to postmarketing surveillance systems monitored by individual corporate sponsors, the FDA and the CDC have developed a national adverse event reporting system for U.S. licensed vaccines.

The ICH E9 guidelines^[42] include specific recommendations on safety evaluation in clinical trials that pertain to both drugs and vaccines. Safety is always an important consideration in vaccine trials, although these trials are mostly designed with a sample size related to a primary hypothesis of efficacy or immunogenicity. It is important to monitor all clinical trials for adverse events that become apparent. Independent data monitoring committees are often established in large multicenter trials to assess the safety and efficacy data at predefined study intervals. The committee may recommend to the sponsor to modify or terminate a trial on the basis of an evaluation of the risks and benefits to the study participants.

The methods and measurements chosen to establish the safety of a vaccine depend on many factors, including the type of vaccine (e.g., live attenuated viruses or bacterial

vaccines) and its specific mechanism for eliciting immune responses. Vaccination can cause allergic or anaphylactic reactions because it induces the immune system. The reactions are typically local to the site of the infection, such as swelling, tenderness, or redness. Systemic reactions, such as fever or muscle ache, can also occur. The vaccine may also produce an illness similar to that produced by the wild-type infectious agent. Coplan et al.^[76] developed and validated a standardized vaccine report card for use in vaccine trials. The pediatric and adult instruments were developed to ensure that the wording was understandable, to promote ease of use, and to enhance accuracy and completeness of reporting. The validation phase showed that the use of a standardized vaccine report card provides a practical and complete method of eliciting complaints after vaccination.

With the increasingly aggressive vaccination schedule in children, an interest in the development of combination vaccines has been expressed. Ellenberg^[77] discussed the statistical considerations in evaluating the safety of combination vaccines. Although combination vaccines generally include individual components that have been previously studied and used, new or more severe adverse reactions might occur in the combination product. Clinical trials usually compare the combination vaccine to the individual components. Although the safety database may not need to be as large as that for the novel vaccines with new immunogens, a reliable evaluation of safety should still be performed. The CBER^[67] developed guidelines for the evaluation of combination vaccines.

All safety variables encountered in a clinical trial require attention, and the protocol should specify the analytical approach. All adverse events should be reported, regardless of whether they are considered related to vaccination. When studies include hypotheses about specific adverse events, the usual statistical framework is appropriate. However, the main difficulty with the statistical analysis of adverse events is the possibility of new and unanticipated reactions. Treating these safety variables as confirmatory information is not appropriate. For this type of safety evaluation, it is best to apply descriptive statistics supplemented by confidence intervals. Measures of risk differences or relative risk are useful for this purpose. Reporting individual p -values can sometimes be used to help evaluate a specific difference of interest or as a “flagging” device applied to many safety variables to highlight possible vaccine effects that are worth further attention.

The ICH E9 guidelines recognize the importance of considering multiplicity in the interpretation of safety data.^[42] They noted the need to quantify the type I error by using statistical adjustments for multiplicity while recognizing the concerns of type II errors in safety assessment. Mehrotra and Heyse^[78] proposed a two-step use of adjusted p -values based on the false discovery rate method of Benjamini and Hochberg^[79] as a flagging method. They used data from three vaccine clinical trials to illustrate

the proposed double false discovery rate approach and to reinforce the potential effect of failure to account for multiplicity.

Because vaccines will typically be administered to millions of otherwise healthy individuals, evaluating vaccines for rare but serious adverse events is important. Common reactions to vaccines are readily identified in the investigational phase of clinical development programs. However, rare but serious events may be missed in the clinical trials. To exemplify the problem, we refer to the “rule of three,”^[80] which states that $3/n$ is an upper 95% confidence bound for the binomial probability P when no events occur among n independent trials. Applying this rule to a vaccine program of $n = 5000$ participants gives an upper bound estimate of $P = 0.0006$ for adverse events not observed in the studies. Administration of the vaccine to 1 million persons could yield 600 severe reactions.

Several activities have been put in place to protect against this situation. Clinical development programs include prelicensed safety studies to build up the safety database. In addition, sponsors undertake Phase IV studies to address important safety concerns. For example, Black et al.^[81] reported the results of a prospective postmarketing evaluation of the safety and effectiveness of varicella vaccination in 89,753 adults and children in the preventive care program of the Northern California Kaiser Permanente Medical Care Program. These types of studies are possible in large managed care organizations because of the large patient populations and the sophisticated use of automated clinical databases of hospitalizations, emergency department visits, and clinic visits. Other types of epidemiologic investigations of vaccine safety are also undertaken. Ascherio et al.^[82] reported the results of a nested case-control study of a possible association between hepatitis B vaccination and the risk of multiple sclerosis. The study was prompted by spontaneous reports of multiple sclerosis development after vaccination. Ascherio et al.^[82] reported no such association in the context of this well-conducted evaluation.

The FDA and the CDC have created the Vaccine Adverse Event Reporting System (VAERS) for postmarketing safety surveillance.^[83] This system accepts reports of adverse events that may be associated with U.S. licensed vaccines from health care providers, manufacturers, and the public. The reports are continually monitored for any unexpected patterns or changes in rates of adverse events. Niu, Eriwn, and Braun^[84] used the empirical Bayes data-mining techniques of DuMouchel^[85] in VAERS to investigate the detection of intussusception after rotavirus vaccination.

Postmarketing evaluations are complex and have their drawbacks.^[86,87] In addition, many persons may be at risk during the early phases of the vaccine integration to the marketplace. Ellenberg^[77] argued that the most reliable way to assess causality in safety is a controlled study and that the size of clinical trials of new vaccines must

be increased to be able to detect serious rare effects. She proposed sample sizes on the order of 60,000 to 80,000 participants using the methods appropriate under simple binomial sampling. This information would increase the confidence in the safety of vaccines and would be a valuable resource for assessing spontaneous reports of adverse events after licensure. Overall, a comprehensive and continual assessment of the safety of a vaccine reduces the risk that a vaccine may cause severe reaction to a small proportion of vaccinees.

The association between rotavirus vaccination and intussusception provides an excellent example of the issues relating to evaluating vaccine safety. Intussusception is a rare but serious bowel condition that occurs in young children 3 mo to 2 yr of age. It occurs when a portion of the bowel folds in on itself and causes a constriction that interrupts blood flow. The incidence of intussusception is approximately 1 case per 2000 person-yr. In prelicensure studies of a rhesus-human reassortant rotavirus tetravalent vaccine (RRV-TV), 5 cases of intussusception were identified among 10,054 vaccinated infants and 1 case was identified among 4633 placebo recipients. This result was not statistically significant, and Rennels et al.^[88] concluded that the findings did not support an apparent association between intussusception and RRV-TV. The RRV-TV was licensed on August 31, 1998, and was recommended by the Advisory Committee on Immunization Practices as a three-dose series given at 2, 4, and 6 mo of age.

Murphy et al.^[89] reported on an investigation that was initiated after 9 cases of intussusception were reported to VAERS. They undertook a thorough data collection exercise and analyzed data for 429 infants with intussusception and 1763 matched controls in a case-control analysis, as well as for 432 infants with intussusception in a case series analysis. A case series analysis^[90,91] estimates the relative incidence of clinical events in defined time intervals after vaccination compared with control periods using only cases. Murphy et al.^[89] concluded a strong causal association between intussusception and RRV-TV vaccination, especially within 1 week after the first dose. Niu, Eriwn, and Braun^[84] used empirical Bayes data-mining methods on the VAERS intussusception data and showed that even earlier detection of rare serious adverse events was possible. The Advisory Committee on Immunization Practices withdrew its recommendation of the vaccine, and the vaccine manufacturer voluntarily withdrew its product from the market.^[92]

Sadoff et al.^[93] described the study design considerations necessary to detect an increased risk of intussusception in a randomized clinical safety study. By using extensive monitoring for intussusception cases through multiple stopping boundaries, they noted that efficiencies in the design are possible. Still, studies to detect rare safety outcomes require very large sample sizes. The complex design described by Sadoff et al.^[93] used Monte Carlo simulation methods for a study that involves at least 60,000 infants. This sample size

is consistent with the sample sizes generally proposed by Ellenberg^[77] for vaccine safety studies.

As a postscript, it is interesting to note that 4 of the 5 cases of intussusception among RRV-TV recipients occurred within 2 weeks of vaccination. The single case in placebo recipients occurred several weeks after vaccination. This observation supports O'Neill's^[94] recommendation to consider the timing of events in the analysis of safety data.

ADDITIONAL STATISTICAL ISSUES FOR ANALYZING VACCINE TRIALS

Intention-to-Treat or Per-Protocol Analysis

A typical intention-to-treat population for vaccine trials includes all randomly assigned participants, regardless of whether they met study entry criteria, the vaccine they actually received, and subsequent withdrawal or deviation from the protocol. In comparison, a typical per-protocol population includes a subset of randomly assigned participants who met the study entry criteria, received study vaccines as prescribed by the protocol, completed the study without major protocol violations, and had endpoint measurements at specific time points. Some vaccine efficacy studies also use a modified intention-to-treat population, which includes only participants who complete all doses of the assigned vaccine and disease cases occurring after some specific time following the full series of vaccination to capture the full effect of the vaccine. More general discussions of these analysis populations in clinical trials can be found in Gillings and Koch,^[95] the ICH E9 guidelines,^[42] Lachin,^[96] and Lange.^[97]

For the analysis of vaccine efficacy, an intention-to-treat analysis generally provides unbiased assessment of vaccination strategy and controls false-positivity rates in placebo-controlled efficacy trials. However, this analysis may artificially inflate the false-positivity rate in trials aimed to show equivalent/noninferior efficacy or immunogenicity of two vaccines. A per-protocol or modified intention-to-treat analysis of vaccine efficacy generally aims to assess the biological effect of the vaccine. Historically, the per-protocol or modified intention-to-treat analysis of vaccine efficacy has often been considered the primary approach, and the intention-to-treat analysis has been considered the secondary approach.^[98] This is probably because bias is less an issue in vaccine trials involving healthy participants; high adherence is usually achievable and missing data/dropouts as a result of adverse experience are usually very low.^[99] In addition, the intention-to-treat and modified intention-to-treat/per-protocol analyses usually yield the same conclusion about the vaccine efficacy. However, if bias is a major concern of the trial (such as in open-label trials), or the goal is to compare the effectiveness of vaccination strategy (such as comparing

a three-dose regimen at 1, 2, and 6 mo versus 2, 6, and 12 mo), then intention-to-treat analysis should be used.^[99]

A per-protocol analysis is usually the primary approach for immunogenicity, which is designed to assess the biological or immunologic effects of vaccination. In addition, an intention-to-treat or modified intention-to-treat analysis is typically planned to support or confirm the per-protocol analysis. Safety analysis of vaccine trials is typically based on a modified intention-to-treat population that includes all participants vaccinated and for whom safety follow-up data are available.

Missing/Coarse Data and Loss to Follow-Up

Missing data and loss to follow-up may occur in vaccine studies. These issues present fewer problems in estimating the efficacy, immunogenicity, or safety of vaccines than in drug trials. Because vaccination is usually administered once or as a few doses over time, treatment adherence is typically very high. In addition, as mentioned earlier, few dropouts are a result of vaccine-related adverse events. In practice, missing data and loss to follow-up from vaccine trials are generally a result of the causes unrelated to the study vaccine. Therefore missing data arising from vaccine trials can reasonably be assumed to be missing at random or even missing completely at random. In an efficacy trial, one can estimate the loss of information (disease cases) because of loss to follow-up and perform sensitivity analyses. Multiple imputation techniques^[100] are useful in these analyses.

Serial-dilution assays are commonly used to measure immune responses. Without a standard curve, the reported immune responses from a serial-dilution assay are often interval-censored, which can be considered as a special form of coarse data.^[101] The lower limit of the interval is routinely reported and treated as the exact titer value in immunogenicity analyses. However, ignoring the coarseness of the immune responses may result in severe bias in parameter estimation. Different approaches have been discussed for addressing this issue.^[102]

Analyses with Stratification Variables

Many vaccine trials are conducted in multiple study centers or are stratified by variables such as age, sex, or other prognostic factors. In these cases, stratified analysis can be used to increase clinical trial (or assay) sensitivity and to reduce estimation bias.^[103,104] An overall vaccine effect can be estimated as a weighted average across strata, and the weighting scheme may depend on whether the stratification factor is prognostic or nonprognostic, or whether treatment-by-stratification interaction exists.^[105–108]

Interim Analyses

In large-scale vaccine efficacy trials, formal interim analyses for potential early stopping of the trial are often

planned. Interim monitoring of efficacy and safety is typically performed by an independent data monitoring committee. The FDA has recently developed a draft guidance on the establishment and the operation of these committees.^[109] Determination of early stopping because of overwhelming efficacy is usually guided by statistical stopping criteria such as those of O'Brien and Fleming^[110] and Lan and DeMets.^[111] Trial termination because of safety concerns occurs far less frequently in vaccine trials than in drug trials because participants receive only one or a limited number of vaccinations over a short period. Of course, futility analysis (for early stopping of the trial because of a low likelihood of success at study end) can be performed to minimize resource utilization.^[112–114]

IMMUNE SURROGATE AND CORRELATE OF PROTECTION FOR VACCINES

A critical task in vaccine development is identifying immune response markers (antibody or T-cell response) that can be used as surrogates for clinical vaccine efficacy so that more efficient evaluation of new vaccines or manufacturing process changes can be performed using the immune surrogates. Immune surrogates are best evaluated in a prospectively planned efficacy trial. The classic methods for validating surrogate endpoints^[115–119] may be used to assess the validity of an immune surrogate. In particular, these methods are applicable for vaccines aimed at increasing the immune responses of persons who may have preexisting immunity; in these situations, the validation criteria are similar to the validation of CD4 counts and viral RNA levels as surrogates for AIDS. However, these classic methods may break down in evaluating pediatric vaccines, which are targeted toward persons who are immune-naïve (without preexisting immunity before vaccination). If a vaccine is highly immunogenic, the immune responses of vaccinated persons will clearly be separated from that of unvaccinated persons (who have no immunity). As a result, the immune response status will be completely confounded with the vaccination status, and it will be very difficult, if not impossible, to apply Prentice's criteria^[115] to show that given an immune response, the probability of developing the disease is the same regardless of whether a person is vaccinated or not.

Because of the above-mentioned reasons, vaccine researchers tend to assess the relationship between immune responses and protective efficacy via the concept of "correlate of protection." By examining vaccine failures, researchers aim to establish a "protective level" of an immune response that can be used to determine whether a person is "completely protected" or "not protected and still susceptible to the disease."^[120–122] On a population basis, this "protected level" means that 100% of the persons who have immune responses at this level or higher will be completely protected from the disease.

In some instances, it is difficult to identify a clear-cut value of the immune response as the "protective level" because protective efficacy tends to increase with higher immune responses. For example, clinical trials with a live attenuated varicella (Oka/Merck) vaccine have shown a high protective efficacy against chickenpox^[31–33] and an inverse relationship between the frequency of chickenpox breakthroughs among vaccinees and the post-vaccination antibody titer measured by the glycoprotein enzyme-linked immunosorbent assay.^[123–125] However, no particular level of antibody can be considered a clear-cut "protective level." Chan et al.^[124] have proposed the use of statistical models (such as accelerated failure time models) to link the whole distribution of antibody titers and long-term disease protection conferred by vaccination, and Li et al.^[125] have proposed the use of the concept of "approximate protective level" at which a high proportion (e.g., > 95%) of individuals are expected to be protected from the disease. If feasible, the use of placebo group and different vaccine dosages in the same study will also enhance the assessment of the immune correlate. Once an immune marker is validated as a "correlate of protection," vaccine efficacy can be subsequently evaluated through this immune marker. This will facilitate efficient evaluation of vaccine manufacturing process changes, vaccine consistency lots, concomitant vaccination, or new combination vaccines. Chan et al.^[124] have also proposed the use of statistical models to predict vaccine efficacy based on the immune responses collected in immunogenicity trials.

ECONOMIC EVALUATION OF VACCINE

There is increasing interest in conducting economic evaluations of medical interventions. Several textbooks review the study types and methods used to evaluate the cost effectiveness of health care programs.^[126–128] Cost-effectiveness analysis identifies all relevant costs involved and evaluates the expected health gains derived in particular programs. The goal of economic evaluation is to maximize the health benefits per dollar spent. The usual measure is the cost-effectiveness ratio, defined as the ratio of the incremental costs of undertaking the health care program to the incremental health effects. Cost-effectiveness analysis is often used as an aid to national public health decision making.

Edmunds, Medley, and Nokes^[129] argued that while most cost-effectiveness analyses are based on the benefits to individual persons for vaccine programs, the population is the appropriate target for the mass immunization program. Therefore the indirect effects (herd immunity) are important and should be included in the cost-effectiveness analysis. This approach measures the health effect of the vaccination program in terms of the proportion of the total population that will be protected after mass immunization. The effects are a result of both the efficacy of the vaccine

and a reduction in the number of infectious individuals in the population. Edmunds, Medley, and Nokes^[129] called this a dynamic model of an infectious disease and showed that the cost-effectiveness ratio seen with the use of this approach tends to decline over time.

Using the dynamic approach involves developing a population-based mathematical model of the spread of the infection. Halloran et al.^[130] developed such a model for routine varicella immunization of preschool children in the United States. Using newly available data, Brisson et al.^[131] updated Halloran et al.'s estimates. The Halloran model has been used as the basis for conducting cost-effectiveness analysis of varicella vaccinations in several countries.^[132]

Cluster Randomized Trials: Sample Size

Sin-Ho Jung

Department of Biostatistics and Bioinformatics, Duke University, Durham, North Carolina, U.S.A.

Abstract

In a cluster randomization trial, clusters consisting of multiple subjects are randomized to two or more treatment arms, and observations are collected from the subjects of each cluster while receiving the same intervention. In such a trial, inferences are usually made at subject level while randomization is done at cluster level. Since the subjects in each cluster share some common frailties, their responses are usually positively correlated, both the sample size calculation and the subsequent statistical analysis must take into account the correlation. In this chapter, we investigate some estimators of binary response rate and sample size method for comparing the response rates between two arms using these estimators when the number of subjects is random among clusters.

Keywords: Binary data; Intraclass correlation coefficient; Varying cluster size; Weighted estimator.

1 INTRODUCTION

Over the past decades there has been increasing popularity of cluster randomization trials in various clinical fields including dentistry and ophthalmology. In such trials, clusters consisting of multiple subjects, called subunits, are randomized to two or more treatment arms, and observations are collected from the subjects of each cluster while receiving the same intervention. So, inferences are usually made at subunit level while randomization is done at cluster level. Since the responses of subjects within a cluster are usually positively correlated due to the shared factors among them, both the sample size calculation and the subsequent statistical analysis must take into account the intraclass dependency among subunits.

In estimating sample size for cluster randomization trials one usually assumes that the number of subunits within each cluster, called cluster size, is constant across clusters for simplicity. However, cluster sizes are not constant in many cluster randomization trials. The sample size formula with for binary outcomes with equal cluster size m is obtained by the standard formula developed for studies randomizing subjects by a variance inflation factor, $[1 + (m - 1)\rho]$, where ρ is the intraclass correlation coefficient (ICC). When the cluster sizes vary, one may replace m with an estimate of the average cluster size as in Manatunga et al.^[1] This approximation is likely to underestimate the actual required sample size (Donner and Klar^[2]).

When cluster size varies among clusters, Kang, Ahn and Jung^[3] evaluated investigated naive sample size calculation methods assuming that cluster sizes are fixed at its mean value or its maximum value. Ahn, Jung and Kang^[4] proposed

weighted chi-squared test statistics for clustered binary outcomes using equal weights to subunits, weights to clusters, and optimal weights. In this chapter, we present a sample size formula for each of these weighted chi-squared tests.

We may choose a time to event variable as the primary endpoint of a cluster randomization trial. Jung and Jeong^[5] proposed weighted log-rank tests and Jung^[6] proposed a sample size calculation method for cluster randomization trials with a time to event endpoint.

2 WEIGHTED CHI-SQUARED TEST STATISTICS

In this chapter, we assume that clusters are randomized between two treatment arms, but the extension to more than two arms is straightforward. Suppose that n_k clusters are randomized to arm k ($= 1, 2$), and cluster i ($= 1, \dots, n_k$) in arm k has m_{ki} subunits. For subunit j ($= 1, \dots, m_{ki}$) of cluster i ($= 1, \dots, n_k$) in arm k ($= 1, 2$), let y_{kij} be a binary random variable taking 1 for response and 0 for no response. By clustered data, we assume that $(y_{ki1}, \dots, y_{kim_k})$ have a common marginal response probability $P(y_{kij} = 1) = p_k$ and an ICC, $\rho_k = \text{corr}(y_{kij}, y_{kij'})$ for $j \neq j'$. We want to test $H_0: p_1 = p_2$ vs. $H_1: p_1 \neq p_2$. Let $y_{ki} = \sum_j y_{kij}$, $y_k = \sum_i y_{ki} = \sum_i \sum_j y_{kij}$, $M_k = \sum_i m_{ki}$, $M = M_1 + M_2$ and $n = n_1 + n_2$.

Let $\hat{p}_{ki} = m_{ki}^{-1} \sum_{j=1}^{m_{ki}} y_{kij}$ denote an estimator of p_k from cluster i in arm k . Jung and Ahn^[7] propose a family of weighted estimator of p_k

$$\hat{p}_k = \frac{\sum_{i=1}^{n_k} w_{ki} \hat{p}_{ki}}{\sum_{i=1}^{n_k} w_{ki}},$$

where $w_{ki} \geq 0$ are weights assigned to cluster i in arm k . Jung, Kang and Ahn^[8] propose a sample size method for one-sample testing using the weighted estimator. Using these results, Ahn, Jung and Kang^[4] develop weighted chi-squared test statistics Z^2 to compare response rates between two arms, where

$$Z = \frac{\sqrt{n}(\hat{p}_1 - \hat{p}_2)}{\sqrt{\hat{\sigma}_1^2 + \hat{\sigma}_2^2}}$$

Where $\hat{\sigma}_k^2 = n \sum_{i=1}^{n_k} w_{ki}^2 \hat{\sigma}_{ki}^2 / \left(\sum_{i=1}^{n_k} w_{ki} \right)^2$ is a variance estimator of $\sqrt{n} \hat{p}_k$,

$$\hat{\sigma}_{ki}^2 = \frac{\hat{p}\hat{q}\{1 + (m_{ki} - 1)\hat{p}\}}{m_{ki}}$$

is a variance estimator of $\hat{p}_{ki}$, $\hat{p} = \sum_{k=1}^2 \sum_{i=1}^{n_k} w_{ki} \hat{p}_{ki} / \sum_{k=1}^2 \sum_{i=1}^{n_k} w_{ki}$ is an estimator of response probabilities under H_0 : $p_1 = p_2$, and $\hat{q} = 1 - \hat{p}$. Under H_0 , for large n_1, n_2 , Z approximately $N(0, 1)$. Hence, we can reject H_0 if $|Z| > z_{1-\alpha/2}$, the $100(1 - \alpha/2)$ -th percentile of $N(0, 1)$.

Weights $w_{ki} = m_{ki}$ assign equal weights to subunits, $w_{ki} = 1$ assign equal weights to clusters, and

$$w_{ki} = \frac{\hat{\sigma}_{ki}^{-2}}{\sum_{i'=1}^{n_k} \hat{\sigma}_{ki'}^{-2}}$$

yield an optimal test statistic, where

$$\hat{\sigma}_{ki}^2 = \frac{\hat{p}\hat{q}\{1 + (m_{ki} - 1)\hat{p}\}}{m_{ki}},$$

$\hat{p}$ is an estimator of ICC. One of most popular ICC estimators is the analysis of variance (ANOVA) estimator, given by

$$\hat{p} = \frac{\text{msc} - \text{mse}}{\text{msc} + (\tilde{m} - 1)\text{mse}},$$

where

$$\text{msc} = \sum_k \sum_i m_{ki} (\hat{p}_{ki} - \hat{p}_k)^2 / (n - 2),$$

$$\text{mse} = \sum_k \sum_i y_{ki} (1 - \hat{p}_{ki}) / (M - n),$$

$$\tilde{m} = \left(M - \sum_k M_k^{-1} \sum_i m_{ki}^2 \right) / (n - 2), \hat{p}_{ki} = y_{ki} / m_{ki} \text{ and } \hat{p}_k = y_k / M_k.$$

3 SAMPLE SIZE CALCULATION

We derive a sample size formula of the weighted chi-squared tests assuming equal ICC with ρ for the two arms and a nearby alternative hypothesis $\sqrt{n}(p_1 - p_2) = o_p(1)$. Let $a_k = n_k/n$ denote the allocation proportion of arm k . Then, $\hat{\sigma}_k^2$ converges to

$$\sigma_k^2 = a_k^{-1} E(w_{ki}^2 \hat{\sigma}_{ki}^2) / \{E(w_{ki})\}^2$$

It is easy to show that

$$\sigma_k^2 = \frac{\bar{p}\bar{q}\{(1-\rho)\mu_{(1)} + \rho\mu_{(2)}\}}{a_k \mu_{(1)}^2}$$

for $w_{ki} = m_{ki}$,

$$\sigma_k^2 = \frac{\bar{p}\bar{q}\{(1-\rho)\mu_{(-1)} + \rho\}}{a_k}$$

for $w_{ki} = 1$, and

$$\sigma_k^2 = \frac{\bar{p}\bar{q}}{a_k \gamma}$$

for the optimal weights, where $\bar{p} = a_1 p_1 + a_2 p_2$, $\mu_{(l)}$ denotes the l -th moment of distribution of cluster sizes m_{ki} and

$$\gamma = E \left\{ \frac{m_{ki}}{(1-p) + m_{ki}p} \right\}.$$

Given n , the power of a test with a 2-sided significance level α is

$$1 - \beta = \bar{\Phi} \left(z_{1-\alpha/2} - \frac{\sqrt{n}\Delta}{\sqrt{\sigma_1^2 + \sigma_2^2}} \right),$$

where $p_1 - p_2 = \Delta$ under H_1 , $\bar{\Phi}(\cdot)$ is the survivor function of the standard normal distribution, and $\sigma^2 = a_k \sigma_k^2$. Hence, the sample size is given as

$$n = \frac{\sigma^2 (z_{1-\alpha/2} + z_{1-\beta})^2}{a_1 a_2 \Delta^2} \quad (1)$$

or $n_k = a_k n$.

In summary, the sample size calculation for a cluster randomization trial may be proceeded as follows.

- Select a test statistic to be used for the final analysis
- Specify design parameters
 1. $\Delta = p_1 - p_2$ under H_1
 2. $(\alpha, 1 - \beta)$

Table 1 Distribution of cluster sizes, $f(m) = P(m_{ki} = m)$

m	5	6	7	8	9	10	11	12	13
$f(m)$	2/32	1/32	3/32	2/32	7/32	9/32	2/32	3/32	3/32

3. ICC ρ
4. Distribution of m_{ki}
5. Allocation proportions (a_1, a_2)
- Calculate the sample size using formula (1)

4 EXAMPLE

Suppose that we want to develop a teratologic animal study to randomize pregnant rats between a control diet and a chemically treated diet during pregnancy and lactation, and compare the 21-day survival rates of the pups between the two arms. We take the data from Weil^[9] to specify the design parameters for our study. Based on the Weil^[9] data, we assume $\rho = 0.25$ and a distribution of cluster sizes, $f(m) = P(m_{ki} = m)$, as given in Table 1. Suppose that we want to show that the 21-day survival rate is about $p_1 = 0.9$ for the control diet and $p_2 = 0.75$ for the chemically treated diet. Under this design setting, we have $\bar{p} = 0.825$, $\mu_{(-1)} = 0.112$, $\mu_{(1)} = 9.47$, $\mu_{(2)} = 94.03$, and $\sigma^2 = 4.929 \times 10^{-2}$ for the equal weights to subunits, $= 4.823 \times 10^{-2}$ for the equal weights to clusters, and $= 4.802 \times 10^{-2}$ for the optimal weights. Hence, for $(\alpha, 1 - \beta) = (0.05, 0.9)$ and a balanced allocation $a_1 = a_2 = 1/2$, we need $n = 92$ ($n_1 = n_2 = 46$), $n = 90$ ($n_1 = n_2 = 45$) and $n = 88$ ($n_1 = n_2 = 44$) using equal weights for subunits, equal weights for clusters and optimal weights, respectively.

Abstract

This entry provides several examples of cluster trials and considers, in detail, the design and analysis of a cluster trial in which an intervention is targeted at changing physician behavior to increase cancer screening in primary medical care practice settings.

INTRODUCTION

Cluster trials are studies that evaluate interventions delivered to intact social groups or clusters, such as communities, churches, schools, workplaces, and medical practices, while outcomes are measured on members of those groups. Today, cluster trials are conducted in social science, medicine, public health, and, to a growing degree, biopharmaceutical science. Cluster trials have been known by many names including “cluster-unit trials,” “cluster-randomized trial,” “group-randomized trials,” and “community trials.” The latter term recognizes the long history of cluster trials in assessing the effect of social interventions in communities. While “cluster trial” may be the most generic term used, it reflects the diversity of settings that use cluster assignment to test interventions. Examples of cluster trial settings include randomized trials with a small number of clusters, non-randomized trials with many clusters, and many settings (e.g., medical practices) where the ratio of the number of clusters in a trial to the average number of subjects per cluster is somewhere along the spectrum between the relative extremes of the typical longitudinal study (large ratio) and the classical community trial (small ratio). This article provides several examples of cluster trials and considers, in detail, the design and analysis of a cluster trial in which an intervention is targeted at changing physician behavior to increase cancer screening in primary medical care practice settings.

The distinctive feature of cluster trials is the presence of intraclass correlation (ICC) among members within groups that arises from restricting randomization to groups instead of to individuals. The ICC will increase the variance of a statistic for assessing intervention beyond what would be expected with random assignment of members to intervention conditions. For clusters of equal sizes m in a posttest-only design, the variance inflation factor (VIF), also referred to as the design effect (DE),

is $\varphi = 1 + (m - 1) \rho$, where ρ is denoted as ICC. Ignoring the correlation associated with clustering may lead to inflation of type I error or the increased chance to declare a statistically significant difference among treatment conditions when no such difference exists. Assignment of interventions by cluster, instead of by individual, decreases statistical power. Therefore to achieve a pre-specified level of power, the total number of individuals enrolled in a cluster trial must exceed the number enrolled in a comparable clinical trial that assigns treatments to individuals. Both the design and analysis of cluster trials require special care.

Another common feature of cluster trials is the small number of clusters enrolled as compared with a relatively large number of subjects within clusters. Many community trials enroll 10 communities or fewer because of the prohibitive financial costs and logistical challenges associated with implementing an often multifaceted intervention to inhabitants of sizable geographic areas, such as villages, towns, cities, or regions. These studies may enroll several hundreds of subjects per community. This feature contrasts with the data structure associated with clustered data from a longitudinal study where individuals are the clusters and each has maybe three, four, or five observations. Because of the large cluster sizes in cluster trials, the presence of a typically small intraclass correlation translates into a substantial design effect that must be considered in the design and statistical analysis. In effect, design and analysis considerations are driven mainly by the number of clusters as opposed to the total number of individuals. Moreover, with a small number of clusters, the degrees of freedom available to estimate cluster-level statistics for assessing treatment differences are limited.

Much as randomization is a cornerstone of the individual-randomized clinical trial, so randomization is applied, when possible, to the cluster trial. Randomization of clusters to intervention conditions lends significant scientific credibility to the study and its subsequent evaluation.

This is especially so when the number of clusters is small. However, in this context, there is no guarantee that simple randomization will result in important baseline covariates being balanced across treatment conditions. Therefore consideration has been given to alternative randomization schemes, including randomization by stratification and within matched pairs. Statistical analysis should consider adjusting for baseline imbalance between treatment groups likely to be present.

WHY ARE CLUSTER TRIALS CONDUCTED?

Given the reduction in statistical power associated with cluster trials, there must be clear motivation for conducting a cluster trial vs. an individual randomized trial. Three reasons a cluster trial may be deemed necessary are as follows: (i) the inherent nature of the intervention; (ii) administrative, political, or ethical considerations; and (iii) concern for the scientific integrity of the study such as issues of blinding. Some cluster trials are motivated by multiple reasons.

Interventions in many trials are, by nature, group-oriented. For example, the COMMIT Trial was a randomized community trial designed to bring diverse organizations, institutions, and individuals together to conduct activities to encourage smoking cessation among the residents of 22 communities.^[1] The philosophy behind the multifaceted intervention was that the community-wide messages against smoking would reach the vast majority of residents and would alert smokers to opportunities for cessation. Similar multi-level community-wide strategies have been employed to reduce underage drinking.^[2,3]

Many cluster trials in the medical practice setting also employ interventions that are, by nature, group-oriented. For example, an intervention may attempt to change physician behavior by targeting medical office practice patterns, while outcomes are collected on patients through surveys or their medical charts. Recognizing that physicians may be at different stages in their readiness to change practice behavior, the Partners for Prevention Project (PARTNERS) employed a multifaceted intervention designed to increase their cancer screening behavior.^[4] The outcomes, measured on a sample of patients in a practice, were whether or not they had been screened for different types of cancer. The cholesterol education and research trial (CEART) is a cluster randomized trial testing the effectiveness of translating the ATP III (Adult Treatment Panel III) cholesterol guidelines into clinical practice, with primary care physician practices as the unit of randomization and patients as the unit of data collection. The prevention arm received an intervention of academic detailing, a computerized patient activation tool placed in the primary care providers office waiting room, and an interactive ATP III Cholesterol Guideline decision support tool made for a hand help device (PDA); the usual care arm received minimal

academic detailing, no computerized patient activation tool, and a PDA without any guidelines.^[5] A multifaceted intervention was also used in a cluster randomized trial to increase physician compliance to guidelines for prescribing antihypertensive and cholesterol-lowering drugs for the primary prevention of cardiovascular disease.^[6]

Cluster trials are used in public health studies to combat infectious diseases because interaction among members within communities means that community indices of health are of primary concern. A cluster trial in 10 communities in Uganda tested whether community-level control of sexually transmitted diseases via a mass antibiotic treatment program would reduce the incidence of HIV infection.^[7] Although drugs were administered within families, the intervention conditions were assigned at the community level because infection rates in communities were the outcomes of interest. In a study to combat sexually transmitted diseases through the promotion of female condom use in 12 agricultural villages in Kenya, political considerations led to a randomized cluster trial.^[8] Because village leaders, religious leaders, and teachers have pronounced influence on inhabitants, it was felt important to include, as part of the intervention, interviews seeking their opinions. Interventions were assigned at the village level in part because of the political consideration to be all inclusive in these communities where social networks were very strong. An education program based on group meetings was employed. A third example is a matched-pair cluster trial in which villages in northwest Iran were randomized to intervention or control with the goal to evaluate the effects of insecticide-impregnated dog collars of reducing the incidence rate of leishmaniasis, an infectious disease, in children.^[9] Transmission is by the bite of a sand fly, and domestic dogs were the principal host. The study showed that application of the collars to all domestic dogs in the intervention villages reduced infection in children of those villages relative to control villages. Villages were separated by distances greater than sand fly flight ranges supporting the use of villages as clusters.

Some interventions are applied at the level of individuals, but because of concerns for the scientific integrity of the study, the intervention conditions are assigned to groups of individuals. A common concern is bias that may result from cross-contamination of the treatment conditions. If subjects who receive the control treatment are in close contact to those that receive the intervention, then the former may become exposed to the intervention and a biased estimate of the treatment effect may result. Although an individual randomized trial would have been possible in the Kenyan female condom use study, contamination within sites was a concern. On the other hand, little contamination was expected in the community trial because “sites were distant enough to preclude social or sexual contacts between intervention and control participants, none of whom own private vehicles.” In an intervention study comparing two preoperative drug regimens

for an eye disease, groups of patients undergoing surgery in the same day were randomized to the same regimen to address concern about the possibility of incorrect regimen assignments because of the heavy volume of daily operations.^[10]

COMMON CLUSTER TRIAL DESIGNS

Study designs for cluster trials can be classified as single-point or multiple time-point designs and as to whether any form of stratification or matching is used. The two most common designs for multiple time-point cluster trials are the nested cross-sectional and nested cohort designs. In both designs, the same clusters are followed over time. In a nested cross-sectional design, different random samples of subjects are selected within each cluster over time, whereas in a nested cohort design, the same subjects are followed over time. There are many factors to consider in choosing between these two designs. These include the rate of attrition of study subjects, length of the trial, population stability, effect of measurement on future responses, statistical efficiency, cost, and objective of the study.^[11] Cross-sectional designs are used when the focus is on the change in a population over time. Cohort designs address questions of within-individual change, and they are more powerful barring dropout. However, a long intervention period might result in substantial dropout in a cohort design.^[12] Because each has its relative strengths and weaknesses, the design of the COMMIT trial incorporated both cross-sectional and cohort components. In the Kenyan female condom use study, creation of cohort of female employees took advantage of the stable populations of permanent employees at the 12 sites, along with the relatively short intervention period.^[8] Many cluster randomized trials in medical practices such as the CEART trial use nested cohort designs with a limited number of clusters.^[5] However, the PARTNERS trial used repeated cross-sectional samples because the focus of inference was on physician screening rates and not on individual patients.^[4]

Studies having a single time point have been called posttest-only designs.^[13] For example, there is no baseline response in the cohort component of the COMMIT trial because all persons were smokers at baseline. Other studies record baseline outcome variables but do not use these data in the primary analysis. If a study randomizes a large number of groups in each condition, then randomization will likely have made the communities in the conditions comparable at baseline. Because the inclusion of the outcome at baseline as a response variable in the model typically reduces power to detect an intervention effect, the analyst may not want to include it unless inclusion is deemed necessary. On the other hand, use of the baseline value of the primary outcome as a covariate in the model for the individual level data, possible in a cohort but not a cross-sectional design, may increase statistical power.

Matching is a common design strategy in cluster trials with a few to moderate number of clusters. In matched-pair cluster randomized trials, pairs of clusters are matched with respect to one or more cluster characteristics that may be linked to the outcome. Within pairs, one cluster is randomized to intervention and the other receives control. Well-made matches not only diminish the chance of baseline imbalance in covariates, but also increases statistical power to detect an intervention effect. Assessment of smoking quit rates in the COMMIT trial of the intervention was based on 11 matched community pairs with matches based on population size and baseline smoking prevalence. In the insecticide-impregnated dog collar trial, villages were matched according to baseline infection rates. Matching in the design does not necessarily need to be followed by a matched-pair analysis. If matches were ineffective, then a matched-pair analysis may be less statistically efficient than an unmatched analysis.^[1] In the case of trials with small numbers of clusters, matching may be overused. For example, loss to follow-up of a single member of a pair may lead to a serious power loss.

STATISTICAL ANALYSIS OF CLUSTER TRIALS

There are several statistical approaches to the analysis of cluster-unit trials. Direct hypothesis testing approaches include tests applied to cluster summary statistics and variants of common tests applied to individual-level data that are adjusted for clustering. Alternatively, modeling approaches for individual level data are broadly applicable because they can easily handle covariates, unequal cluster sizes, and multiple time points or treatment conditions. Models that are extensions of generalized linear models provide the context for hypothesis tests of intervention effects using population-averaged or conditional models. For simplicity, we restrict attention to cluster trials with only two treatment conditions: intervention and control. Binary outcomes are treated here because analogous methods for continuous responses tend to be better established.

Cluster-Level Analysis

One approach to the analysis of cluster trials is to treat the cluster as the unit of analysis by creating a summary statistic for each cluster such as the proportion of respondents in the cluster exhibiting the outcome following the treatment, in the case of a binary response. For unmatched studies, the standard two-sample *t*-test may be used to compare intervention and control conditions. One criticism of this approach is that the assumptions that the cluster-specific event rates are normally distributed with equal variances are not strictly satisfied. These assumptions will clearly be violated if there is variation in cluster sizes. However, when the number of clusters assigned to each intervention group is equal, the *t*-test is known to be fairly robust to

violations of the underlying assumptions.^[12] The t -test also applies to unweighted cluster-level mean responses for continuous outcomes.^[12]

The parametric assumptions of the t -test may be avoided by using non-parametric procedures such as the Wilcoxon rank sum test. Randomization tests, which use the actual values of observations rather than their ranks, tend to be more powerful.^[12] In the COMMIT trial, randomization tests were applied to the within matched-pair difference in community level smoking quit rates.^[1] Exact p -values are determined from the permutation distribution of the test statistic under the null hypothesis of no difference between conditions. These summary statistic methods may be adapted to adjust for individual-level covariates.^[1]

Adjusted Chi-Square Test for Individual-Level Data

Another approach to the analysis of binary outcomes in cluster trials is to adjust the standard Pearson chi-square test for the clustering effect. Let $\hat{P}$ be the overall event rate observed in the study, $\hat{P}_k$, $k = 1, 2$, be the event rates for the k th treatment condition, and M_k be the total number of individuals in condition k . Then an adjusted one degree of freedom chi-square statistic is

$$\chi_A^2 = \sum_{k=1}^2 \frac{M_k (\hat{P}_k - \hat{P})^2}{\phi_k \hat{P}(1 - \hat{P})} \quad (1)$$

where the correction factor ϕ_k depends on the intraclass correlation and the cluster sizes.^[12] In the case of equal cluster sizes m , $\phi_1 = \phi_2 \equiv \phi$, and $\phi = 1 + (m - 1)\rho$, where ρ is the average pairwise correlation within clusters assumed to be constant across clusters. The parameter ϕ is known as the variance inflation factor because it represents the multiplicative factor by which the variance of cluster summary statistics are inflated because of the correlation arising from the cluster design relative to a study design that randomizes treatments to individuals who are statistically independent of one another. If the data are uncorrelated ($\rho = 0$), then Eq. 1 is the standard chi-square test. An estimate of ρ can be obtained by applying standard analysis of variance to the binary outcomes:

$$\hat{\rho} = \frac{MSB - MSW}{MSB + (m - 1)MSW} \quad (2)$$

where

$$MSB = \sum_{k=1}^2 \sum_{i=1}^{n_k} m (\hat{P}_{ki} - \hat{P}_k)^2 / (K - 2) \quad (3)$$

and

$$MSW = \sum_{k=1}^2 \sum_{i=1}^{n_k} m \hat{P}_{ki} (1 - \hat{P}_{ki}) / (M - K) \quad (4)$$

where $\hat{P}_{ki}$ is the event rate observed for the i th cluster in the k th condition, n_1 and n_2 are the number of clusters assigned to the intervention and control conditions, respectively, $M = M_1 + M_2$, and $K = n_1 + n_2$ is the total number of clusters. For continuous responses, the two-sample t -test can be adjusted with a measure of the pooled variance that depends on an estimate of ρ .^[12] The ICC can also be estimated when cluster sizes are variable.^[12]

Individual-Level Analysis with Population-Averaged Models

The population-averaged or marginal model approach extends generalized linear models to account for clustered data. Population-averaged models provide a natural approach for the analysis of cluster-unit trials because differences in population means or proportions between intervention and control conditions are typical parameters of interest. A population-averaged model parameter for the intervention effect describes how the response average changes across various subsets of the study population where subsets are defined by covariate values. These models are commonly estimated with the generalized estimating equations procedure.^[14] Let $\mathbf{Y}_i$ be the response vector for cluster or community $i = 1, \dots, K$, where $\mathbf{Y}_i = (Y_{i1}, \dots, Y_{ij}, \dots, Y_{im_i})$ is the vector of responses from the m_i individuals in the i th cluster. Let μ_i be the vector of population marginal means, $E[\mathbf{Y}_i] = \mu_i$. A generalized linear model is $g(\mu_{ij}) = X_{ij}'\beta$ where $g(\cdot)$ is the link function and X_{ij} is the $p \times 1$ vector of covariates for the j th individual in the i th cluster. Estimation of β is performed by solving

$$\sum_{i=1}^K \mathbf{D}_i'(\mathbf{X}_i, \beta) \mathbf{V}_i^{-1} [\mathbf{Y}_i - \mu_i(\beta)] = 0 \quad (5)$$

where $\mathbf{D}_i(\mathbf{X}_i, \beta) = \partial \mu_i / \partial \beta$, $\mathbf{V}_i = \mathbf{A}_i \mathbf{R}_i \mathbf{A}_i'$, where $\mathbf{A}_i = \text{diag}\{v_{ij}^{1/2}\}$ is a diagonal matrix with $v_{ij} = \text{var}(Y_{ij})$ and $\mathbf{R}_i(\alpha)$ is a working correlation matrix that depends on an unknown nuisance parameter vector α . For binary data, $v_{ij} = \mu_{ij}(1 - \mu_{ij})$. The GEE estimate $\hat{\beta}$, solved by iteratively reweighted least squares, has an asymptotically Gaussian distribution with mean β and covariance matrix estimated by $(\sum_{i=1}^K \mathbf{D}_i' \mathbf{V}_i^{-1} \mathbf{D}_i)^{-1}$, the model-based variance estimator which provides valid inference when $\mathbf{R}_i$ is correctly specified [i.e., $\text{corr}(\mathbf{Y}_i) = \mathbf{R}_i$]. Otherwise $\text{var}(\hat{\beta})$ may be estimated by the “robust” or empirical covariance estimator^[15,16] that consistently estimates $\text{var}(\hat{\beta})$ even if $\mathbf{R}_i(\alpha)$ does not equal the true correlation matrix. This strategy permits the use of simple working models for the correlation structure which is considered a nuisance factor in the analysis that tests for intervention effects.

The most common specification of α for a cluster trial is a single parameter, $\rho = \text{corr}(Y_{ij}, Y_{ij'})$, denoting a common or exchangeable correlation, for all pairs of elements from $\mathbf{Y}_i$. A common approach is to use simple method-of-moment

estimators for the elements of α ,^[15] however, this procedure does not provide standard error estimates. Standard errors are desirable to provide information regarding a plausible range of correlation values when performing sample size calculations in planning future cluster trials. In the case of binary data, define the $[m_i(m_i - 1)/2 \times 1]$ vectors $\mathbf{Z}_i = \{Z_{i12}, Z_{i13}, \dots, Z_{i(mi-1)mi}\}'$ and $\rho_i = \{\rho_{i12}, \rho_{i13}, \dots, \rho_{i(mi-1)mi}\}'$ where $Z_{ijj}' = r_{ij}r_{ij}'$, $r_{ij} = (Y_{ij} - \mu_{ij})/[\text{var}(Y_{ij})]^{1/2}$, and $\rho_{ijj}'(\alpha) = E[Z_{ijj}']$. A formal specification of the GEE is completed by defining estimating equations for the correlation parameters α :^[17]

$$\sum_{i=1}^K \mathbf{E}_i' \mathbf{W}_i^{-1} [\mathbf{Z}_i - \rho_i(\beta, \alpha)] = 0 \quad (6)$$

where $\mathbf{E}_i = \partial \rho_i / \partial \alpha$ and $\mathbf{W}_i$ is a working covariance matrix for $\mathbf{Z}_i$. The form of $\mathbf{E}_i$ in Eq. 6 is determined from the model for the pairwise correlation. Here the pairwise correlations are modeled as a linear function of pair-specific (typically, cluster-specific) covariates. The combination of Eqs. 5 and 6 gives consistent estimation of β even if the model for α is misspecified. A common working covariance matrix $\mathbf{W}_i$ is given by a diagonal matrix with elements

$$\text{var}(Z_{ijj}') = 1 + (1 - 2\mu_{ij})(1 - 2\mu_{ij}')\{\mu_{ij}(1 - \mu_{ij}')\mu_{ij}' \times (1 - \mu_{ij}')\}^{-1/2} \rho_{ijj}' - \rho_{ijj}'^2 \quad (7)$$

Use of weights $\mathbf{W}_i = \mathbf{I}_{mi(mi-1)/2}$ and a further refinement for the correction factor p gives the all-available-pairs correlation estimator.^[18] Empirical standard errors for α are used because $\mathbf{W}_i$ is a diagonal working correlation matrix.^[17]

One approach with GEE is to avoid estimation of α by using a working independence matrix and the empirical variance estimator for $\hat{\beta}$. However, modeling the correlation structure may increase statistical efficiency of the GEE regression parameter estimates.^[15] Another advantage with the second approach is that the correlation estimates may be used in statistical power calculations to plan future studies.^[3] Finally, estimation of α from a carefully specified model enables one to use the model-based variance estimator for $\hat{\beta}$. It may have performance superior to the robust variance estimator because the latter is an inefficient estimator of the true variance when cluster sizes are large.^[16]

Individual-Level Analysis with Mixed Effects Models

The subject-specific or mixed effects model approach extends generalized linear models to account for clustered data through specification of random cluster effects. A generalized linear mixed model (GLMM) is $g(\nu_{ij}) = \mathbf{X}_{ij}'\beta^* + \mathbf{Z}_{ij}'\mathbf{U}_i$ where ν_{ij} denotes $E(Y_{ij}|U_i)$. The GLMM for cluster trials^[19,20] assumes the following: (i) the conditional distribution of Y_{ij} given U_i , given by $f(y|U)$, follows an

exponential family generalized linear model; (ii) given U_i , the responses from a cluster Y_{ij} , $j = 1, \dots, m_i$, are independent; and (iii) the U_i are independent and identically normally distributed with density $f(U_i; \gamma)$ having covariance matrix G . The likelihood function is a function of the unknown parameters β^* and the parameter elements of γ of G , and the data $\mathbf{Y} = (\mathbf{Y}_1', \dots, \mathbf{Y}_K')'$:

$$L[\beta^*, \gamma, \mathbf{Y}] = \prod_{i=1}^K \prod_{j=1}^{m_i} f(Y_{ij} | U_i; \beta^*) f(U_i; \gamma) dU_i \quad (8)$$

Because the random effects, U_i , are not observed, they are integrated out to obtain the likelihood for the observable $\mathbf{Y}_i$, $i = 1, \dots, K$. This integration is difficult when $\mathbf{Y}_i$ is not normally distributed; in these cases, numerical approximation is used because the integral has no closed form. Linear mixed model analysis is well established for cluster unit trials with continuous responses.^[11,13]

The choice between population-averaged and subject-specific models should be based on the scientific question of interest. Use of a non-linear mixed effects model leads to regression parameters that have simple interpretations for covariates that vary within a cluster. However, for covariates that do not vary within clusters, the interpretation of such cluster-specific coefficients can be difficult or misleading because they measure a contrast in covariates when the random effects are controlled for, that is, are held equal. Intervention status of a community is a cluster-specific variable in cluster-unit trials because each community is studied under exactly one condition. The mixed logistic model gives an intervention effect whose meaning is conditional on the random effect and so the interpretation is restricted to the particular community, or, more broadly, to the conceptual population of communities with the same values of the unobserved random effect. The contrast of interest relies on the difference in the response under intervention and control conditions for a given cluster, clearly a non-observable event. For this reason, a population-averaged model has been recommended for the analysis of cluster-specific covariates.^[21,22]

There are other important differences in the analysis of cluster trials between the two general approaches. The regression parameters in the population-averaged model and the conditional model are different parameters with $\beta \neq \beta^*$, generally. In particular, the logistic-normal mixed model for binary data tends to give intervention parameter estimates that are larger than their population-averaged model counterparts. Specifically, for the random intercept model with $U_i \sim N(0, \sigma^2)$, $\beta \approx \beta^* / \sqrt{1 + 0.35\sigma^2}$.^[22] Finally, aside from the linear model and a few simple cases of the loglinear model for Poisson data, there are no simple relationships between variance components from generalized linear mixed models and marginal correlations defined for the distinct types of pairs of observations in a cluster.^[23]

For cluster trials with continuous response variables, mixed linear models are commonly used.^[13] If the design is balanced, exact tests are available with analysis of variance techniques. Generally, however, regression parameters in mixed linear models are estimated using maximum likelihood techniques. Regression parameters in these models, which are also called hierarchical linear models, have both population-averaged and conditional model interpretations, and unlike the binary data case, $\beta = \beta^*$. While GEE may be used for linear models, mixed model analysis is usually chosen because of its superior finite sample properties when the likelihood is correctly specified. Sandwich variance estimation may be used in mixed model analysis if robustness to the assumed covariance structure is desired.

DETERMINING SAMPLE SIZE

Taking the intracluster correlation into account in the planning phase of a study is critical because failure to do so may result in an underpowered study. The number of clusters in each condition (assuming $n_1 = n_2 \equiv n$) needed for testing the intervention with equal numbers of clusters per group using a two-sided test with α significance level and power $1 - \beta$ is

$$n = \frac{\phi(\sigma_1^2 + \sigma_2^2)(z_{1-\alpha/2} + z_{1-\beta})^2}{m\delta^2} \quad (9)$$

where m is the number of subjects per cluster, $\phi = 1 + (m - 1)\rho$, $\sigma_k^2 = \text{var}(Y_{ij} | \text{condition } k)$, δ is the difference to be detected, and z_c is the $(100 \times c)$ th percentile of the standard normal distribution. Furthermore, let $\Phi(\cdot)$ define its cumulative distribution function. Power $(1 - \beta)$ is given by

$$1 - \beta = \Phi\left(\frac{\delta}{\sqrt{\phi(\sigma_1^2 + \sigma_2^2) / nm}} - z_{1-\alpha/2}\right) \quad (10)$$

In the case of continuous outcomes, equal variance ($\sigma^2 \equiv \sigma_1^2 = \sigma_2^2$) is usually assumed and δ is the hypothesized difference in intervention and control population means.^[12] When n is small, use of the t -distribution instead of the normal distribution will improve these calculations. For binary data, Eq. 9 becomes

$$n = \frac{\phi\{P_1(1 - P_1) + P_2(1 - P_2)\}(z_{1-\alpha/2} + z_{1-\beta})^2}{m(P_1 - P_2)^2} \quad (11)$$

using the event rate notation of “Adjusted Chi-Square Test for Individual-Level Data.”

Often in primary care, the number of clusters (practices) is fixed. Based on Eq. 11, the cluster size m is derived:

$$m = \frac{(1 - \rho)\{P_1(1 - P_1) + P_2(1 - P_2)\}(z_{1-\alpha/2} + z_{1-\beta})^2}{n(P_1 - P_2)^2 - \rho\{P_1(1 - P_1) + P_2(1 - P_2)\}(z_{1-\alpha/2} + z_{1-\beta})^2}$$

Note that the denominator could be negative. That means n is too small, such that for the given α , one could not achieve the desired power $1 - \beta$ for any value of m .

Extensions of this formula for pretest-posttest cluster trial designs are available.^[13]

ANALYSIS OF CANCER SCREENING DATA

A representative sample of over 100 non-academic family physicians and general internists throughout Colorado was randomly assigned into four treatment conditions directed at physician and office practice behavior to increase screening for breast, cervical, prostate, and skin cancer. One physician was selected per primary care medical practice. The data considered here involve 1,209 patients from the 55 physicians that received either the control or full intervention condition; data on two partial intervention conditions are not included. Control refers to usual care, while intervention involved regional orientation and continuing contact by telephone and office visits at six-month intervals over a two-year period from 1992 to 1994. From each practice, medical charts from approximately 22 male and 22 female patients between the ages of 42 and 74 were selected at each of three time points, baseline (preintervention), and one and two years post intervention.

The analysis considers one outcome from the female patients, a binary indicator for clinical breast exam within the year previous to the year 2 follow-up study visit. Observed screening rates were $\hat{P}_1 = 266 / 594 = 44.8\%$ in the intervention group, $\hat{P}_2 = 252 / 615 = 41.0\%$ in the control group, and $\hat{P}_2 = 518 / 1209 = 42.8\%$ overall. A naive analysis of these data ignores possible intrapractice correlation of responses; the Pearson chi-square test statistic is 1.787 ($p = 0.181$). The conclusion from this incorrect analysis is that the intervention did not significantly increase screening for breast cancer with clinical breast exam. The incorrect analysis is liberal because it ignores the positive intrapractice correlation. Applying a standard two-sample t -test to the physician level screening rates in Table 1 comparing the unweighted mean screening rates of 44.78% for intervention practices and 40.99% for control practices gives $t = 0.70$ ($p = 0.488$). Alternatively, the ANOVA estimate of the intracluster correlation is $\rho = 0.125$, and the adjusted chi-square statistic is $\chi_A^2 = 0.494$ ($p = 0.482$). Thus relative to the results of these two tests, the naive analysis gives an inappropriately small p -value.

The GEE approach is to test the intervention with hypothesis test $H_0: \beta_1 = 0$ in the context of the logistic model:

$$\text{logit}(\mu_{ij}) = \beta_0 + \beta_1 x_{1i} \quad (12)$$

where $\mu_{ij} = E(Y_{ij}) = P(Y_{ij} = 1)$ is the probability of clinical breast exam in the preceding year for the j th patient in the

i th practice in the intervention ($x_{i1} = 1$) or control group ($x_{i1} = 0$) at posttest. The analogous GLMM is

$$\text{logit}(v_{ij}) = \beta_0^* + u_i + \beta_1^* x_{i1} \quad (13)$$

where $v_{ij} = E(Y_{ij}|u_i) = P(Y_{ij} = 1|u_i)$ is the conditional probability of clinical breast exam in the preceding year for the j th patient in the i th practice. Table 2 reports the results of each of these models. Although intervention practices had higher rates of clinical breast exam, results of both models show that the difference between intervention and control practices in screening rates was not statistically significant. From the GEE analysis, a randomly selected woman from an intervention practice had an estimated $\exp(0.155) = 1.168$ times higher odds to be current for clinical breast exam than a randomly selected woman from a control practice (95% confidence interval: 0.761–1.792). The interpretation from the GLMM is somewhat different: a randomly selected woman under the intervention condition had an estimated $\exp(0.168) = 1.182$ times higher odds to be current for clinical breast exam than a randomly selected woman from the same practice under the control condition (95% confidence interval: 0.722–1.938). This odds ratio represents a contrast that is not observed in the data because each practice is observed under exactly one condition. The presence of the practice random effect u_i in the model means that β_1^* is the log odds of cancer screening for the i th practice. The population average intercept as estimated from the GLMM is $-0.4203 / \sqrt{1 + 0.35\sigma^2} = -0.420 / 1.133 = -0.371$ which is close to the estimate from GEE ($\hat{\beta}_0 = -0.365$). The population average intervention effect as estimated from the GLMM is $-0.168 / 1.133 = 0.148$ which is reasonably close to the GEE estimate ($\hat{\beta}_1 = 0.1551$). Differences may

be a result of the bias inherent in the respective estimation methods, including the approximation involved in evaluating Eq. 8 in fitting the GLMM.

Suppose now that a future intervention is planned to increase clinical breast exam rates among female patients and sample size calculations are required. Assume the control group screening rate is $P_1 = 0.41$ and the follow-up visit intervention group screening rate is $P_2 = 0.51$. Power calculations are based on the GEE estimate $\hat{\rho} = 0.12$ and additional values that are the estimated upper and lower 95% confidence limits, 0.07 and 0.17. For example, using Eq. 10 with $\sigma_k^2 = P_k(1 - P_k)$, $\delta = 0.10$, and $\rho = 0.12$, $n = 62$ medical practices per study condition would provide 80% power for a two-sided 0.05 significance level test for a two-condition cluster trial with $m = 22$ patients per practice. Fig. 1 presents power as a function of n and ρ . A curve for $\rho = 0$ illustrates how failing to account for intraclass correlation can result in gross overestimation of study power. Lastly, an estimate of ICC from the

**Fig. 1** Power for binary outcome, $m = 22$ individuals per cluster

GLMM results, for a latent continuous outcome, is given by $\hat{\rho} = \hat{\sigma}^2 / \{[\hat{P}(1 - \hat{P})]^{-1} + \hat{\sigma}^2\} = 0.138$.^[13]

OTHER ISSUES IN CLUSTER TRIALS

Multiple Time Points

Both the GLMM and GEE approaches allow specification of general models for the mean structure. For cluster trials with multiple time points, a model may include terms for the intercept, time effects, main effects for conditions, and time by condition interactions. In the GLMM approach, specification of multiple random effects accounts for different sources of variation arising from multiple time-point designs.^[13] This provides a correlation structure that is richer than the simple exchangeable correlation. Implementation of GEE with commercially available software has been more restricted with respect to providing realistic correlation structures for multiple time-point cluster trials. GEE methods and sample size formulae specifying correlation structures based on certain study designs have been proposed.^[3] Use of GEE based on Eqs. 5 and 6 provides estimation in general correlation models.

Adjusting for Covariates

Analysis with mixed models or GEE can accommodate cluster-level or individual-level covariates. The multiple time-point nested cohort design is a special case that allows one to model the change score from baseline as a response variable. Modeling baseline response as a covariate may increase precision and power. More generally, including covariates in the model that are correlated with the response may increase statistical power as well as adjust for baseline imbalances. In non-randomized trials, it is important to adjust for covariates to account for imbalance in the treatment assignment.

Non-Randomized Trials

Randomization, a common feature in cluster trials, is not always possible. In large government- and foundation-sponsored cluster trials, the intervention communities are sometimes chosen by administrators of such funds.^[3] Study investigators may then only choose the comparison communities for the evaluation. A consequence of cluster non-randomized trials is that clusters selected to receive intervention may differ from those not selected with respect to baseline covariates. Those differences may lead to biased estimates of intervention effect. Traditional methods of adjustment, matching, stratification, and covariance analysis, may be employed. One large non-randomized study to reduce underage drinking used propensity scores to choose the control communities for evaluation.^[3]

Finite Sample Performance

Particularly in cases of unbalanced or categorical data, inference for cluster trials relies on test statistics with approximate distributions. Valid inference based on GEE or GLMM methods requires that K is sufficiently large. Likelihood ratio tests in GLMM analyses may be unreliable in small samples.^[12] Obtaining valid inference with GEE and using empirical sandwich covariance estimation require approximately 40 clusters,^[20,24] otherwise, the sandwich estimator tends to underestimate the true variance. This, in turn, tends to increase the type I error of the Wald test that uses the sandwich estimator. Mancl and DeRouen and Kauermann and Carroll have proposed alternative bias-corrected covariance estimators for a small sample of clusters.^[16,25] Simulation study results for cluster trials show that these bias-corrected covariance estimators perform better than uncorrected sandwich estimators in terms of bias and coverage probabilities.^[26] Additionally, introduction of bias-correction into the estimating equations for the intraclass correlations may considerably improve their point and interval estimation.^[27]

Cluster Trials in Pharmaceutical Studies

Due to inherent features of pharmaceutical product development processes, cluster trials are seldom used in pharmaceutical studies. Recently, some community based cluster trials were designed to evaluate interventions to improve the effectiveness and safety of drugs. Mullany and colleagues have reported a community-based cluster trial to assess the effects of 4.0% chlorhexidine on omphalitis and mortality risk among newborns in southern Nepal.^[28] Clarke and colleagues designed a double-blind cluster-randomized trial in 30 primary schools in western Kenya to evaluate the effect of intermittent preventive treatment in reducing anemia and improving classroom attention and educational achievement in semi-immune schoolchildren. Schools were randomly assigned to treatment (sulfadoxine-pyrimethamine in combination with amodiaquine or dual placebo), and the prevalence of was assessed through cross-sectional surveys 12 months post-intervention.^[29] Another cluster trial has been used to evaluate the effectiveness of educational outreach visits to improve adverse drug reaction (ADR) reporting by pharmacists in Portugal. Four spatial-clusters of pharmacists were assigned to the intervention group and eleven to the control group. The intervention took the form of hour-long educational outreach visits tailored to training needs detected in a previous study, with a 13- to 16-month follow-up period.^[30]

CONCLUSION

Cluster trials are used in many areas of health research, and they have a particularly strong tradition in behavioral

and disease prevention research. By contrast, there are fewer cluster pharmaceutical trials; this article has briefly described some that have been conducted in recent years. Although cluster pharmaceutical trials have been mostly used in community settings in developing countries, their use is likely to broaden.

The primary feature of the cluster trial is the intracluster correlation that arises from assignment of treatment conditions to intact groups of individuals. This means that special consideration is needed in the planning and conduct of such trials that is not required in a clinical trial that randomizes treatments to individuals. Because of such challenges, research in how to best plan and analyze data from cluster trials will continue. This is especially true for categorical outcomes and in those situations characterized by a small number of clusters, each with a large number of subjects per cluster.

Abstract

Presented in this entry is a review of existing methods for power analysis with a focus on regression and correlation analysis. Also discussed is the latest development in addressing the random missing data pattern.

INTRODUCTION

Power analysis for sample size calculation is an important component in the design and planning of modern clinical trials. It provides information for assessing the feasibility of a study to detect some prespecified effect size and for estimating the amount of resources necessary for its execution in both efficacy and effectiveness research. Over the past two decades, studies in biomedical, pharmacologic, and psychosocial research have evolved from simple cross-sectional to more elaborate longitudinal study designs. As longitudinal designs use subjects as their own controls, such study designs afford a unique opportunity to examine changes of outcomes of interest over time, providing critically important information for research in these areas such as modeling disease progression, treatment response patterns, treatment tolerability, and toxic side effects. However, such study designs have also brought about several methodologic issues, the most prominent of which are data clustering and missing data.

Although the past two decades have witnessed major advances in the development of statistical methods for addressing data clustering, particularly for longitudinal studies, most research efforts have been centered around data analysis, with little attention to power and sample size estimation. As a result, the latter development has been progressing at a much slower pace. Often, methods developed based on cross-sectional study designs are used to provide power and sample size estimates for longitudinal trials. Only recently has attention been paid to the effects of within-subject correlation (or intracluster variability) and missing data in such study designs. However, despite the heightened attention and nascent efforts, some critical issues remain unresolved, particularly the random missing data pattern.

In this article, we review existing methods for power analysis with a focus on regression and correlation analysis. In addition, we discuss our latest development in addressing the random missing data pattern. For convenience of exposition, we have organized the presentation into two parts, with Part I devoting to regression and Part II to correlation analysis. We illustrate the methods discussed with several examples that are motivated by real trials in biomedical and psychosocial research.

PART I. POWER ANALYSIS FOR REGRESSION MODELS

Consider a study of n clusters, indexed by i , each of size m ($1 \leq i \leq n$). Let Y_{it} denote the response and X_{it} the vector of predictors (or covariates) of the t th member from the i th cluster.

In statistics, the notion of cluster is a generic term used to describe groups of subjects and/or data that are more similar within each group than across different groups. The existence of such clusters invalidates the usual independent sampling assumption, and as a result, statistical methods developed based on independence of observations such as in most cross-sectional studies are no longer applicable to such data. Longitudinal studies are the most popular examples involving data clustering, as repeated assessments of an individual over time give rise to clustered responses.^[1] Clustered data also often arise from cross-sectional study designs, as in epidemiologic and psychosocial research, where subjects sampled from a common habitat such as families, schools, and communities are more similar than those from different habitats.^[2,3] For convenience, we assume no additional data clustering for longitudinal

studies other than repeated assessments and single-level data clusters (i.e., no nesting) for cross-sectional studies. Such an assumption applies to most of the study designs in practice. As single-level data clusters in cross-sectional studies can be treated as a special case of data clusters of longitudinal study designs,^[4] we will focus on the latter study designs only. We first review methods for power analysis in the absence of missing data.

Complete Data Case

Consider a longitudinal study with n subjects and m prespecified assessment times $t = 1, \dots, m$.

Let Y_{it} denote the response and $X_{it} = (X_{it1}, \dots, X_{itp})^\top$, the vector of covariates or explanatory variables from the i th subject at t th assessment. In many studies, the X_{it} may consist of baseline covariates and deterministic functions of such variables and time. Two most popular approaches for longitudinal study data are the generalized estimating equations (GEE) and mixed-effects models (MM).^[1,5–21] For data analysis, the latter class of models has the advantage of delineating the between- from the within-cluster variability, while the former has the much desired distribution-free property for providing robust inference about the between-cluster variability. In many applications, power analysis is usually conducted for detecting between-cluster variability, or differences in the expected value of the response. Thus, the advantage of MM in obtaining intraclass variance estimates is no longer an important consideration. On the other hand, the distribution-free property of GEE becomes especially desirable for power analysis; without real data, it would be impossible to validate a parametric model, and such a robust property will ensure more reliable estimates. Of course, the final decision on which approach to take ultimately rests upon which approach will be used for data analysis; it makes little sense to compute power based on an MM, when the study data will eventually be analyzed by GEE.

Regardless of which approach to use, we consider regression models that link X_{it} to Y_{it} through a linear predictor $X_{it}^\top \beta$ or a function of such a predictor, where β is the vector of parameters of interest. Under GEE, such a regression for a continuous, binary or count (frequency) response is defined by the marginal mean and variance of the response in terms of a generalized linear model:^[11,21]

$$\begin{aligned} E(Y_{it} | X_{it}) &= h(X_{it}^\top \beta) = h_{it}, \\ \text{Var}(Y_{it} | X_{it}) &= \lambda^2 v(h_{it}), \quad 1 \leq i \leq n, \quad 1 \leq t \leq m \end{aligned} \quad (1)$$

where $h^{-1}(\cdot)$ is a known link function, λ^2 , a scale parameter, and $v(\cdot)$ is a known function.^[22] Under MM, the within-subject correlations of the joint distribution of the repeated responses are explicitly accounted for by introducing some latent variables (random effects). For a continuous response, the linear mixed-effects model (LMM) is defined by

$$\begin{aligned} Y_{it} &= X_{it}^\top \beta + Z_{it}^\top \mathbf{b}_i + \epsilon_{it} \text{ or } Y_i = X_i \beta + Z_i \mathbf{b}_i + \epsilon_i, \\ \mathbf{b}_i &\sim N(0, D), \quad \epsilon_i = (\epsilon_{i1}, \dots, \epsilon_{im})^\top \sim N(0, \sigma^2 I_m), \\ 1 &\leq t \leq m \end{aligned} \quad (2)$$

where D denotes the variance of the random effect $\mathbf{b}_i$, σ^2 , the variance of the model error ϵ_i , I_m , the $m \times m$ identity matrix, and $X_i = (X_{i1}, \dots, X_{im})^\top$ and $Z_i = (Z_{i1}, \dots, Z_{im})^\top$ are the design matrices for the fixed and random effect, respectively. Note that in Eq. (2), we have assumed that ϵ_{it} has a constant variance σ^2 . If this variance changes over time, the discussion to follow still applies, with $\sigma^2 I_m$ replaced by a diagonal matrix with σ_t^2 of on the t th diagonal.

As in Ref. [4], we limit our discussion of mixed-effects models to LMM in this article. A primary reason for focusing on LMM rather than more general mixed-effects models such as the generalized linear mixed-effects models for discrete responses is the large number of different approaches proposed for inference and the complexity of the asymptotic distributions of model estimates.^[5–9,12,14,18–20] Also, for GEE, we limit our consideration to Eq. (1) for continuous, binary or count responses. The proposed approach is readily generalized to GEE models for categorical responses.^[13]

For power analysis, we consider the class of general linear hypothesis of the form

$$H_0 : K\beta = 0, \quad H_a : K\beta = a \neq 0 \quad (3)$$

where K is a known full rank $s \times p$ matrix and a some $s \times 1$ vector of known constants. The linear contrasts (3) apply to virtually all types of hypotheses concerning β in practical studies.^[4]

Generalized Estimating Equations

Under GEE, estimates of β are obtained as solutions to the following estimating equations

$$U(\beta) = \frac{1}{n} \sum_{i=1}^n U_i = \frac{1}{n} \sum_{i=1}^n D_i^\top V_i^{-1} S_i = 0 \quad (4)$$

where

$$\begin{aligned} A_i &= \text{diag}[v(h_{it})], \quad Y_i = (Y_{i1}, \dots, Y_{im})^\top, \\ h_i &= (h_{i1}, \dots, h_{im})^\top, \quad V_i = A_i^{-1} W(\alpha) A_i^{-1}, \\ D_i &= \frac{\partial}{\partial \beta^\top} h_i, \quad S_i = Y_i - h_i, \quad U_i = D_i^\top V_i^{-1} S_i \end{aligned} \quad (5)$$

In Eq. (5), $\text{diag}[v(h_{it})]$ denotes a diagonal matrix with $v(h_{it})$ on the t th diagonal and $W(\alpha)$ a working correlation matrix modeled by the parameter vector α . The working correlation matrix, $W(\alpha)$, is generally not equal to the true within-subject correlation of Y and its role is to increase efficiency.^[11,23] Note that for power analysis, λ^2 and α are all specified so that Eq. (4) is a function of β only.

A GEE estimate, $\hat{\beta}$ obtained as a solution to Eq. (4), is both consistent and asymptotically normal, i.e.,

$$\begin{aligned} \sqrt{n}(\hat{\beta} - \beta) &\rightarrow_d N(0, \Sigma_\beta = B^{-1} \Sigma_U B^{-1}) \\ B &= E(D_1^\top V_1^{-1} D_1), \Sigma_U = E(D_1^\top V_1^{-1} D_1) \\ \Sigma_U &= E(D_1^\top V_1^{-1} S_1 S_1^\top V_1^{-1} D_1) \end{aligned} \quad (6)$$

where $\rightarrow_d$ denotes convergence in distribution.^[24,25] For data analysis, α , B , and Σ_U are estimated by the observed data. When their estimates are substituted into Eq. (6), we obtain a robust asymptotic variance estimate of Σ_β . For power analysis, there is typically no data to estimate these parameters. Thus, to evaluate Σ_U , we must model the true conditional variance $\text{var}(Y_i | X_i)$ in addition to $W(\alpha)$. Two extreme cases are worth noting: (1) $W(\alpha)$ is the true correlation matrix and (2) $W(\alpha)$ is set equal to the identity matrix (working independence assumption). Although achieving maximum power, it is unrealistic to expect that a selected $W(\alpha)$ is the true correlation matrix. Thus, the identity matrix choice for $W(\alpha)$ may be preferable in real study designs to provide more realistic and useful power estimates. The asymptotic variance for each of the two case scenarios is given by

$$\Sigma_\beta = \begin{cases} E^{-1} [D_1^\top \text{Var}(Y_i | X_i) D_1] & \text{if } W(\alpha) \text{ is true correlation} \\ B^{-1} E^{-1} [D_1^\top A_1^{-1} \text{Var}(Y_i | X_i) A_1^{-1} D_1] B^{-1} & \text{if } W(\alpha) \text{ is set to identity matrix} \end{cases}$$

where E^{-1} denotes the inverse of the expectation and $B = E(D_1^\top A_1^{-1} D_1)$.

Under H_0 and H_a in Eq. (3), the quadratic

$$Q_n^2 = n \hat{\beta}^\top K^\top (K \Sigma_\beta K^\top)^{-1} K \hat{\beta} \quad (7)$$

has an asymptotic central and non-central χ_s^2 distribution, respectively,

$$H_0 = Q_n^2 \sim \chi_s^2(0), \quad H_a = Q_n^2 \sim \chi_s^2(c) \quad (8)$$

where $c = n a^\top (K \Sigma_\beta K^\top)^{-1} a$, a is the non-centrality parameter. Let $F_{\chi_s^2(c)}^2$ denote the cdf of $\chi_s^2(c)$. The power function, φ , for the linear contrast (3) for an α level of type I error is given by

$$\begin{aligned} \varphi(n, c, \alpha) &= 1 - F_{\chi_s^2(c)}^2(p1 - \alpha), \\ \alpha &= 1 - F_{\chi_s^2(0)}^2(p1 - \alpha) \end{aligned} \quad (9)$$

where p_γ denotes the γ th percentile of $\chi_s^2(0)$.

For a given sample size n , φ above provides the power for detecting H_a in Eq. (3). Alternatively, Eq. (9) can also be used to estimate the required sample size to achieve a prespecified power.^[4] In this case, φ is given, and the

minimum sample size required to reach φ is the solution to the first equation in (9). This non-linear equation is numerically solved by root-finding methods such as the Newton's algorithm.^[26] Most commercially available software packages implement one or more such root-finding methods. For example, in SAS, the function NLPFDD computes the root of a general non-linear function using Newton's method, where the required first-order derivatives are either analytically calculated or numerically approximated, depending on the complexity of the non-linear function. Sample size estimates are obtained by rounding off the solutions using the largest integer function. Later in this article, we will give some similar power functions in various situations, and the required sample sizes to achieve prespecified powers can be similarly computed.

Linear Mixed-Effects Model

Let $V_i = Z_i D Z_i^\top + \sigma^2 I_m$. For power analysis, D and σ^2 are known, and the maximum likelihood estimate (MLE) of β is given by Laird and Ware^[10] and Kowalski et al.^[27]

$$\hat{\beta} = \left(\sum_{i=1}^n X_i^\top V_i^{-1} X_i \right)^{-1} \left(\sum_{i=1}^n X_i^\top V_i^{-1} Y_i \right) \quad (10)$$

In addition, $\hat{\beta}$ has the limiting distribution

$$\sqrt{n}(\hat{\beta} - \beta) \rightarrow_d N(0, \Sigma_\beta = E^{-1} [X_1^\top (Z_1 D Z_1^\top + \sigma^2 I_m)^{-1} X_1]) \quad (11)$$

The Wald statistic Q_n^2 defined in Eq. (7) again has an asymptotic χ_s^2 distribution, except for a redefined Σ_β given by Eq. (11). The power function is again given by Eq. (9). Evaluation of Σ_β has been discussed in Ref. [4].

Missing Data Case

In almost all longitudinal clinical trials, missing data are inevitable, no matter how well a trial is planned and executed. One common approach to account for the effect of missing data is simply inflate sample size calculated based on complete data so that the adjusted sample size has a built-in protection against the loss of power owing to missing data. For example, if we anticipate that 10% of the subjects will drop out, we can use a sample size so that the trimmed 90% of the subjects will be sufficient to achieve a prespecified power. This approach, however, assumes that only subjects with complete data will be used for analysis, which is too conservative since GEE and LMM can use all available data. In addition, it does not account for the effect of missing data patterns. Consider for example the missing data patterns shown in Fig. 1 from a hypothetical study with three assessments on each of six subjects. Although the same proportion of total measurements (2/3) is missing

at each assessment point across the patterns, the power to detect between-assessment differences could differ greatly between the patterns. For example, the unbalanced case in (b) generally yields more power than (a), because the observations in (b) are obtained from distinct rather than the same clusters (individuals) as in (a). Although patterns (b) and (c) involve the same number of clusters, they will also yield different power functions if we are interested in testing differences between the means at different assessment points. For the three patterns in Fig. 1, the trimmed approach to inflate sample size is only appropriate for pattern (a).

Unlike data analysis where inference is typically conditioned on observed data, missing data patterns are completely unknown when planning a real study. The three scenarios in Fig. 1 are among the many possible patterns for the hypothetical study. For power analysis, we must consider these plus many more as potential missing data patterns. Currently, there is no general approach for addressing the random missing data patterns. Existing methods provide power estimates either conditional on a particular missing data pattern or based on certain marginal distributions of missing data patterns.^[28–30] As different missing data patterns generally give rise to different power functions, none of these approaches sufficiently addresses the dynamic nature of missing data patterns. For example, one such strategy is to condition on the available sample size at each assessment point. Clearly, such an approach does not distinguish the first two patterns in Fig. 1. Although methods developed for survey research and epidemiologic studies do account for differences in the number of clusters as well as cluster size,^[3,31] they do not address the time-ordered structure in longitudinal data. For example, patterns (b) and (c) are the same in terms of number of clusters and cluster size in each cluster. But, as noted earlier, the two patterns generally give rise to different power functions.

Recently, we developed a new approach to address the random missing data pattern. This approach explicitly models the random missing data pattern using random

indicators and integrates the missing data model into the power function. We outline this approach below. More details can be found in Ref. [32].

Define a vector of binary variables for indicating missing (or rather observed) data for each subject as follows.

$$r_{it} = \begin{cases} 1 & \text{if } Y_{it} \text{ is observed} \\ 0 & \text{otherwise, } \mathbf{r}_i = (r_{i1}, \dots, r_{im})^\top, \\ & R_i = \text{diag}(r_{it}), \quad 1 \leq i \leq n \end{cases} \quad (12)$$

For convenience, denote the baseline by $t = 1$ and assume no missing data at this time point, i.e., $r_{i1} \equiv 1$ ($1 \leq i \leq n$). Each configuration of $\mathbf{r}_i$ determines a missing data pattern and vice versa. In accordance with the literature, we assume that missing data only occurs in the response, not in the covariates. For a real study, $\mathbf{r}_i$ are observed once the study is completed. Data analysis proceeds by conditioning on the observed $\mathbf{r}_i$. For power analysis, $\mathbf{r}_i$ are unknown, and we must consider all possible values of this random vector in constructing the power function. Throughout the rest of the discussion, we assume missing completely at random (MCAR), i.e., given X_i , $\mathbf{r}_i$, and Y_i are independent.^[11,33–35] We discuss extensions to more general missing data mechanisms in section “Discussion.”

Generalized Estimating Equations

Let $\tilde{S}_i$ denote a subvector of S_i containing those S_{it} for which $r_{it} = 1$ ($1 \leq t \leq m$). Similarly, let $\tilde{D}_i$ and $\tilde{V}_i$ be the submatrices of D_i and V_i corresponding to the t s with $r_{it} = 1$ ($1 \leq t \leq m$). In data analysis, Y_{it} with $r_{it} = 1$ represent observed data, and inference about β under GEE is based on the observed-data estimating equations:

$$U(\beta) = \frac{1}{n} \sum_{i=1}^n \tilde{D}_i^\top \tilde{V}_i^{-1} \tilde{S}_i = 0 \quad (13)$$

Under MCAR, Eq. (13) defines a consistent and asymptotically normal estimate of β .^[11,35,36]

For power analysis, $\mathbf{r}_i$ are not observed, which makes Eq. (13) difficult to work with in terms of expressing power as a function of $\mathbf{r}_i$. To illustrate the alternative approach that will be used for the development of power analysis, consider the working independence assumption, i.e., $V_i = A_i$. In this special case, it is readily checked that Eq. (13) is equivalent to

$$U(\beta) = \frac{1}{n} \sum_{i=1}^n D_i^\top R_i V_i^{-1} R_i S_i = 0 \quad (14)$$

The asymptotic distribution of the estimate, $\hat{\beta}$, of the above estimating equations can be expressed as

$$\sqrt{n}(\hat{\beta} - \beta) \rightarrow_d N(0, \Sigma_\beta = B^{-1} \Sigma_U B^{-1}) \quad (15)$$

Subject	Pattern a Assessments			Pattern b Assessments			Pattern c Assessments		
	1	2	3	1	2	3	1	2	3
1	y_{11}	y_{12}	y_{13}	y_{11}	.	.	y_{11}	.	.
2	y_{21}	y_{22}	y_{23}	y_{21}	.	.	y_{21}	.	.
3	.	.	.	.	y_{32}	.	y_{31}	.	.
4	.	.	.	.	y_{42}	.	y_{41}	.	.
5	.	.	.	.	.	y_{53}	y_{51}	.	.
6	.	.	.	.	.	y_{63}	y_{61}	.	.

Fig. 1 Three missing-data patterns for a longitudinal study with six subjects and three assessment points (y_{it} denotes the response of the i th subject at time t with dots denoting missing data)

where B and Σ_U are given by

$$B = E(D_1^T R_1 V_1^{-1} D_1) \\ \Sigma_U = E(D_1^T V_1^{-1} R_1 \text{Var}(Y_1 | X_1) R_1 V_1^{-1} D_1) \quad (16)$$

Unlike Eq. (13), the estimating equations (14) explicitly involve r_{it} so that the asymptotic variance of $\hat{\beta}$ can be expressed as a function of $\mathbf{r}_i$. Given a model for the true variance $\text{Var}(S_i | X_i)$, B and Σ_U in Eq. (16) are readily evaluated. Note that B and Σ_U depend on R_i only through the first two moments of $\mathbf{r}_i$.

For non-diagonal choices of V_i , Eq. (14) is generally different from Eq. (13). Although estimates of β obtained from Eq. (14) are still consistent, they are different from the ones produced by Eq. (13), which are usually used in data analysis. Thus, we focus on the choice of V_i based on the working independence assumption in the discussion to follow. As noted earlier in Section “Complete Data Case,” power derived based on this special case is generally conservative.

The construction of the power function for testing the hypothesis (3) proceeds in the same way as in the complete data case. In particular, the quadratic Q_n^2 is again given by Eq. (7), but with Σ_β redefined by Eqs. (15) and (16). In addition, the form of the power function given in Eq. (9) remains unchanged.

As an example to illustrate the evaluation of B and Σ_U defined in Eq. (16), consider Eq. (1) with the identity link, i.e.,

$$E(Y_{it} | X_{it}) = X_{it}^T \beta, \quad \text{Var}(Y_{it}) = \sigma_i^2, \quad 1 \leq t \leq m, \\ 1 \leq i \leq n \quad (17)$$

The above linear model is quite popular in growth curve analysis. It is readily checked that B and Σ_U in Eq. (16) are given by

$$B = E(X_1^T R_1 A_1^{-1} X_1), \\ \Sigma_U = E[X_1^T A_1^{-1} R_1 \text{Var}(Y_1) R_1 A_1^{-1} X_1] \quad (18)$$

In the complete data case, $R_i = I_m$, and B and Σ_U can be expressed in closed form as a function of the first two moments of X_i .^[4] With missing data, Eq. (18) involves the random matrix R_i . In addition, R_i may depend on X_i , which further complicates the evaluation of these quantities. However, when R_i is independent of X_i , Eq. (18) reduces to

$$B = E(X_1^T E(R_1) A_1^{-1} X_1) \\ \Sigma_U = E\{X_1^T A_1^{-1} E[R_1 \text{Var}(Y_1) R_1] A_1^{-1} X_1\} \quad (19)$$

Both matrices above have a common form $E(X_1^T P X_1)$, where

$$P = E(R_1) A_1^{-1} \quad \text{or} \quad P = A_1^{-1} E[R_1 \text{Var}(Y_1) R_1] A_1^{-1}$$

depending on whether to evaluate B or Σ_U . In either case, P is a constant matrix and is readily expressed in closed form as a function of $\text{Var}(Y_1)$, $E(\mathbf{r}_1)$ and $E(\mathbf{r}_1 \mathbf{r}_1^T)$. Given P , $E(X_1^T P X_1)$ is readily evaluated

$$E(X_1^T P X_1) = \left[g_{lr} = \sum_{s=1}^m \sum_{t=1}^m p_{st} E(X_{1s} X_{1t}) \right] \quad (20)$$

where g_{lr} denotes the lr th element of $E(X_1^T P X_1)$ and p_{st} , the st th element of P . Thus, B and Σ_U are functions of the first two moments of the missing data indicator $\mathbf{r}_1$ as well as the first two moments of X_1 .

The more complex situation with R_i depending on X_i can be similarly discussed.^[32] However, B and Σ_U may not be in closed form, and their evaluations may be facilitated by Monte Carlo approximation.^[4,32]

Linear Mixed-Effects Model

Given D and σ^2 , we can express the MLE of β for the linear mixed-effects model defined in Eq. (2) in terms of the observed data, i.e., Y_{it} with $r_{it} = 1$.^[10,37] However, as in the case of GEE, it is difficult to work with such an expression and its associated asymptotic distributions for power analysis because it does not explicitly involve $\mathbf{r}_i$. Our strategy is to apply the approach developed for GEE to the marginalized linear mixed-effects model, which can be treated as a GEE model with a more structured variance.

To this end, let A_i , V_i , D_i , and S_i be defined in Eq. (5) with $h_i = X_i \beta$, $v(h_i) = Z_i^T D Z_i + \sigma^2$, and $W(\alpha) = I_m$. Consider the estimating equations (14) with these redefined components. The asymptotic distribution of the estimate from Eq. (14) is given by Eq. (15) with

$$B = E(X_1^T R_1 A_1^{-1} X_1) \\ \Sigma_U = E[X_1^T A_1^{-1} R_1 (Z_i D Z_i^T + \sigma^2) R_1 A_1^{-1} X_1] \quad (21)$$

Thus, evaluation of B and Σ_U is similar to Eq. (18) for the linear regression model under GEE (17) except that Eq. (21) has a more structured working variance A_i and true variance $Z_i D Z_i^T + \sigma^2$.

Note that unlike Eq. (17), the true variance now depends on Z_i . In most growth-curve analyses, Z_i is a function of time only and is also functionally independent of X_i . In this case, Eq. (21) can be evaluated in closed form as for the linear GEE model just discussed. When Z_i involves baseline covariates, the distribution of X_i must be known to evaluate Eq. (21). Evaluation of Eq. (21) in this more general case may be facilitated by Monte Carlo approximation.^[4,32]

For the linear contrast (3), the quadratic Q_n^2 defined in Eq. (7) again has an asymptotic χ_s^2 distribution, except for the redefined B and Σ_U given in Eq. (21). In addition, the power function remains the same general form as well.

Modeling Missing Data Indicators with Markov Processes

As seen in the preceding discussion, the asymptotic variance, Σ_{β} , is a function of moments of the missing data indicator $\mathbf{r}_i$. To evaluate these moments, it is convenient to model $\mathbf{r}_i$ using a two-state Markov process because r_{it} is a binary variable.^[38,39]

For $1 \leq s \leq t \leq m$, let

$$\mathbf{P}_i(s, t) = \begin{pmatrix} p_{i11}(s, t) & \bar{p}_{i11}(s, t) \\ p_{i01}(s, t) & \bar{p}_{i01}(s, t) \end{pmatrix},$$

$$p_{ik1}(s, t) = \Pr(r_{it} = 1 | r_{is} = k),$$

$$s < t, k = 0, 1 \quad (22)$$

where $p_{ik1}(s, t)$ is the transition probability from state k at time s to state 1 at time t of r_{it} and $\bar{p}_{ik1} = 1 - p_{ik1}$. We may model the transition matrix $\mathbf{P}_i(s, t)$ differently for different subgroups or even as a function of individual covariates. For convenience, we consider the homogeneous case in which $\mathbf{P}_i(s, t) = \mathbf{P}(s, t)$. In addition, we assume no missing data at baseline $t = 1$ so that $\Pr(r_{i1} = 1) = 1$. Using Eq. (22), we can easily express the moments of $\mathbf{r}_i$ in terms of the transition probabilities

$$E(r_{i1} r_{i2} \dots r_{iK}) = \prod_{k=1}^K p_{11}(t_{(k-1)}, t_k), \quad (23)$$

$$1 \leq t_1 < \dots < t_K \leq m, \quad 1 \leq K \leq m$$

where $t_0 \equiv 1$ and $p_{11}(t_{(-1)}, 1) \equiv \Pr(r_{i1} = 1)$ so that the above also yields a valid expression for $k = 1$.

The Markov model in Eq. (22) involves many parameters and may be difficult to use in the absence of real data as in most applications. One approach to this problem is the one-step Markov model defined by

$$\mathbf{P}(s, t) = \begin{pmatrix} p_{11}(s, t) & \bar{p}_{11}(s, t) \\ p_{01}(s, t) & \bar{p}_{01}(s, t) \end{pmatrix} = \prod_{u=s}^{t-1} \Phi(u),$$

$$\Phi(u) = \begin{pmatrix} \phi_{11}(u) & \bar{\phi}_{11}(u) \\ \phi_{01}(u) & \bar{\phi}_{01}(u) \end{pmatrix}, \quad (24)$$

$$\phi_{k1}(u) = p_{k1}(u, u+1), \quad \phi_{01}(1) = p_{01}(1, 2) = 0$$

$$1 \leq u < t \leq m, k = 0, 1$$

where $\bar{\phi}_{k1} = 1 - \phi_{k1}$. Under Eq. (24), $\mathbf{P}(s, t)$ is determined by the one-step transition probability matrix $\Phi(t)$, with $\phi_{k1}(t)$ describing the one-step transition probabilities from state k at time t to state 1 at $t + 1$, as depicted in Fig. 2. The constraint $\phi_{01}(1) = 0$ reflects the assumption of no missing data at baseline $t = 1$. These $\Phi(t)$ are easy to interpret and readily specified to account for different anticipated missing data processes. For example, by setting $\phi_{01}(t) = \phi_{11}(t)$ ($2 \leq t \leq m$), we model a process in which the occurrence

Fig. 2 One-step Markov model for missing data process with solid line-arrows indicating one-step transition probabilities $\phi_{k1}(t)$ from state k at time $t - 1$ to state 1 at time t of the missing data indicator r_{it} ($k = 0$ for a missing and $k = 1$ for a non-missing response) and dashed line-arrows indicating transitions (with probability $1 - \phi_{k1}(t)$) from state k at time $t - 1$ to state 0 at time t of the missing data indicator

of missing data at time t is independent of the missing data status at the earlier time $t - 1$. By allowing $\phi_{01}(t)$ to differ from $\phi_{11}(t)$, we can accommodate processes where missing data is either more or less likely to occur if it occurs at an earlier time. For example, by specifying $\phi_{01}(t) = 0.5\phi_{11}(t)$, we model a process in which missing data is twice more likely to occur if it occurs at the previous time.

In addition to directly specifying $\Phi(t)$, we may also determine these one-step transition probability matrices so that they yield the prespecified marginal means of $\mathbf{r}_i$. This latter approach has a more transparent interpretation. For example, if we anticipate that an expected q_t percent of data will be missing at time t , i.e., $E(r_{it}) = 1 - q_t$ ($2 \leq t \leq m$), we can solve for $\Phi(t)$ as a function of q_t using the following recursive expression

$$\mathbf{P}(1, t) = \prod_{u=1}^{t-1} \Phi(u) = \mathbf{P}(1, t-1) \Phi(t-1), \quad (25)$$

$$\mathbf{P}(1, 1) = I_2, \quad \phi_{01}(1) = 0, \quad 2 \leq t \leq m$$

where I_2 denotes the 2×2 identity matrix. The above also simultaneously yields $\mathbf{P}(1, t)$ ($2 \leq t \leq m$), which can be used to express the moments of $\mathbf{r}_i$ according to Eq. (23). Note that solving $\Phi(t)$ also requires specifying a relationship between $\phi_{01}(t)$ and $\phi_{11}(t)$ such as $\phi_{01}(t) = \phi_{11}(t)$, as discussed earlier (see Example 1.^[32]).

Note that if the one-step transition matrix is a constant, $\Phi(t) = \Phi$, we obtain a time-stationary Markov model.^[38,39] If in addition, $\phi_{11} = \phi_{01}$, then $\mathbf{P}(s, t) = \Phi$ and $E(r_{it}) = \phi_{11}$. In this special case, missing data occurs at a uniform rate $q = 1 - \phi_{11}$ over time. In addition, the moments in Eq. (23) admit a simpler expression

$$E(r_{i1} r_{i2} \dots r_{iK}) = \phi_{11}^K,$$

$$2 \leq t_1 < \dots < t_K \leq m, \quad 1 \leq K \leq m \quad (26)$$

As before, the case with $\phi_{11} > \phi_{01}$ ($\phi_{11} < \phi_{01}$) would imply that missing data is more (less) likely to occur if it occurs at an earlier time.

PART II. POWER ANALYSIS FOR CORRELATION MODELS

Complete Data Case

Consider a clustered study with n clusters, each of size m . As before, we assume independence across clusters and a common cluster size. Let $\{(X_{it}, Y_{it}); 1 \leq i \leq n; 1 \leq t \leq m\}$ denote a set of paired variables from the i th cluster. We assume that clustered data arise from longitudinal study designs or multivariate responses in cross-sectional studies, with clusters formed by individual subjects. We are interested in examining the changes in correlations $\rho_t = \rho_{xyt} = \text{Corr}(X_{it}, Y_{it})$ between X_{it} and Y_{it} over t .

This general setup applies to both longitudinal and cross-sectional study designs. For example, if n denotes the number of subjects and m the number of assessments in a longitudinal study, then ρ_t represent time-dependent correlations between X_{it} and Y_{it} . As another example for a clustered cross-sectional study design, consider the problem of assessing correlations among three response variables, U , V , and W . Suppose that we are interested in testing the null hypothesis: $H_0: \rho_1 = \rho_2$, where $\rho_1 = \text{Corr}(U, W)$ and $\rho_2 = \text{Corr}(V, W)$. To couch this inference problem within the general setup, simply let

$$m = 2, \quad X_{i1} = U_i, \quad X_{i2} = V_i, \quad Y_{i1} = Y_{i2} = W_i$$

For convenience, we refer to t as time and m as total number of assessments throughout the rest of the discussion.

Let $\rho = (\rho_1, \rho_2, \dots, \rho_m)^\top$. Consider again linear contrasts of the form

$$H_0: K_p \rho = 0 \quad \text{vs.} \quad H_a: K_p \rho = \mathbf{a} \neq 0 \quad (27)$$

where K is some $g \times m$ full rank ($g \leq m$) matrix of known constants and $\mathbf{a}$, a $m \times 1$ vector of known constants. The Pearson correlation is an estimate of ρ , and its asymptotic distribution has been used extensively for inference about ρ , particularly in psychiatric and psychosocial research.^[40–47] Let $\hat{\rho} = (\hat{\rho}_1, \hat{\rho}_2, \dots, \hat{\rho}_m)^\top$, with $\hat{\rho}_t$ denoting the Pearson estimate of ρ_t ($1 \leq t \leq m$). Then, under a multivariate normal assumption for $Z = (Z_1^\top, \dots, Z_m^\top)^\top$, with $Z_t = (X_t, Y_t)^\top$, the asymptotic normal distribution of $\mathbf{r}$ is given by

$$\sqrt{n}(\hat{\rho} - \rho) \rightarrow_d N(0, \Sigma_\rho = [\sigma_{st}])$$

$$\sigma_{st} = \begin{cases} (1 - \rho_s^2)^2 & \text{if } s = t; \\ \frac{1}{2} \rho_s \rho_t (\rho_{xst}^2 + \rho_{yst}^2 + \rho_{xyts}^2 + \rho_{xyts}^2) & \text{if } s \neq t \\ + (\rho_{xst} \rho_{yst} + \rho_{xyts} \rho_{xyts}) - & \\ - \rho_s \rho_{xst} \rho_{xyts} + \rho_{yst} \rho_{xyts} - \rho_t (\rho_{xst} \rho_{xyts} + \rho_{yst} \rho_{xyts}) & \end{cases} \quad (28)$$

where $\rightarrow_d$ denotes convergence in distribution and

$$\begin{aligned} \rho_{xyst} &= \text{Corr}(X_{is}, Y_{it}), \quad \rho_{xst} = \text{Corr}(X_{is}, X_{it}), \\ \rho_{yst} &= \text{Corr}(Y_{is}, Y_{it}), \quad 1 \leq s, t \leq m \end{aligned} \quad (29)$$

To use this asymptotic distribution, we must estimate the parameters in the asymptotic variance Σ_ρ . Let $P_g = [\rho_{gst}]$ ($g = X, Y$) denote the $m \times m$ matrix defined by the within-variable correlations (WVC), ρ_{gst} , and $P_{xy} = [\rho_{xyts}]$, the $m \times m$ matrix defined by the cross-variable correlations (CVC), ρ_{xyts} . Then, Σ_ρ is a function of the elements of these matrices. In addition, ρ corresponds to the diagonal of P_{xy} . With real data as in data analysis, consistent estimates of P_g and P_{xy} are readily computed. When no data is available, such estimates cannot be calculated, and other alternative estimates such as guesses from other similar studies must be considered. Thus, for power analysis, it is desirable to reduce the nuisance parameters as much as possible.

Note that Fisher's z transformation is often applied to improve the accuracy of the asymptotic distribution.^[48–51]

Within our context, this transformation, $T_F \hat{\rho} = \frac{1}{2} \ln \frac{1 + \hat{\rho}}{1 - \hat{\rho}}$,

is applied to each component of $\hat{\rho}$, i.e., $T_F(\hat{\rho})$ is defined as a vector

$$T_F(\hat{\rho}) = \left(\frac{1}{2} \ln \frac{1 + \hat{\rho}_1}{1 - \hat{\rho}_1}, \dots, \frac{1}{2} \ln \frac{1 + \hat{\rho}_m}{1 - \hat{\rho}_m} \right)^\top \quad (30)$$

By applying the Delta method,^[52] we obtain the asymptotic distribution of $T_F(\mathbf{r})$

$$\begin{aligned} \sqrt{n} [T_F(\hat{\rho}) - T_F(\rho)] &\rightarrow_d \\ N(0, \Sigma_{T_F} = D_\rho \Sigma_\rho D_\rho^\top), \quad D_\rho &= \frac{\partial}{\partial \xi} |_{\xi = \rho} T_F(\xi) \\ &= \text{diag}((1 - \rho_t^2)^{-1}) \end{aligned} \quad (31)$$

where $\text{diag}(a_t)$ denotes the diagonal matrix with a_t on the t th diagonal. For notational brevity, the asymptotic distribution (28) will be used in the following discussion.

In most applications, elements of WVC are typically modeled as a function of $|t - s|$, and a wide class of analytic functions is available for modeling $\rho_{gst} = \rho_g(|t - s|)$.^[53] For example, under the uniform compound symmetry assumption,^[1] $\rho_{gst} = \rho_g$ for all $s \neq t$ with $-1 < \rho_g < 1$. Such an assumption may oversimplify the correlation structure, but other alternatives are available to reach a compromise between practical utility and analytic tractability, especially when partial information is available about the variables. Modeling such correlation structure has been extensively discussed in the literature and is not repeated here.

For elements of the CVC P_{xy} , the problem unfortunately is much more complicated, and in particular, is not readily addressed by existing methods such as the approach

used for modeling the WVC. For example, consider a simple case with $m = 2$. If P_{xy} is modeled using a uniform compound symmetry assumption, then the null hypothesis $H_0: \rho_1 = \rho_0, \rho_2 = 1/2\rho_0$ would be contradictory to the assumed model, while $H_0: \rho_1 = \rho_2 = \rho_0$ is implied by such a model ($-1 < \rho_0 < 1$). On the other hand, the unstructured model with no constraint on the elements of P_{xy} would involve too many parameters to be practically useful in most applications. Thus, to use the asymptotic distribution for power analysis, it is desirable to develop an approach that not only reduces the number of parameters in P_{xy} , but also ensures this internal consistency with respect to the hypotheses for ρ .

Surrogacy Assumption

Consider the assumption

$$[Y_t|X_t, X_s] = [Y_t|X_t], \quad 1 \leq s \neq t \leq m \quad (32)$$

where $[Y|X]$ denotes the conditional distribution of Y given X . Although similar in appearance, the above is not a Markov assumption as often seen in stochastic process modeling,^[38] because the conditional distribution involves different rather than the same variable at different times. This condition is known as a surrogacy assumption in measurement error, or errors in variable, models literature.^[28,36,54] Within the current context, Eq. (32) stipulates that X_s contains no additional information that could be predictive of Y_t once X_t is known, i.e., a surrogate of X_t in predicting Y_t .

Under Eq. (32), we can express the elements of CVC P_{xy} in terms of ρ_t and the elements of the WVC P_{xy} by assuming a linear regression model. Let

$$Y_{it} = \beta_{0t} + \beta_{1t}X_{it} + \epsilon_{it}, \quad \epsilon_{it} \sim i.i.d.(0, \sigma_{\epsilon t}^2), \quad 1 \leq i \leq n, 1 \leq t \leq m \quad (33)$$

where (μ, σ^2) denotes a distribution with mean μ and variance σ^2 . Let σ_{gt} denote the standard deviation of g_t ($g = X, Y$). Then, since $\rho_t = \beta_{1t} \sigma_{xt} \sigma_{yt}^{-1}$, it follows from Eq. (32) and the law of iterated expectations that^[52]

$$\begin{aligned} \rho_{xyst} &= \sigma_{xs}^{-1} \sigma_{yt}^{-1} E[(X_s - \mu_{xs})(Y_t - \mu_{yt})] \\ &= \beta_{1t} \sigma_{xt} \sigma_{yt}^{-1} \rho_{xst} = \rho_t \rho_{xst} \end{aligned} \quad (34)$$

The above computations are diagrammatically illustrated in Fig. 3; ρ_{xyst} (dotted line) is calculated as a function of ρ_t (vertical line) and ρ_{xst} (horizontal line). Thus, given P_x , P_y , and ρ , P_{xy} is completely determined by Eq. (34) and is consistent with the hypotheses for ρ . The asymptotic variance of the limiting normal (28) becomes a function of only P_x , P_y , and ρ . Note that in Eq. (33), X_{it} is treated as an independent and Y_{it} , a dependent variable. Similar results are obtained by reversing the roles of the two variables.

Fig. 3 Diagram illustrating the calculation of CVC correlation ρ_{xyst} using WVC correlations ρ_{xst} and ρ_t

In practice, we only need to assume one of the models. For convenience, we assume Eq. (33) in the following discussion. Note also that Eq. (34) follows from Eqs. (32) and (33). Although the reverse in general is not true, i.e., not all linear regression models satisfy Eq. (32), a large class of linear models does.^[55]

Power Functions Based on Asymptotic and Empirical Distributions

For the class of linear contrasts (27), it follows from the discussion in Part I that under H_0 and H_a , the quadratic quantity $Q_n^2 = n(K\hat{\rho} - \mathbf{a})^T(K\Sigma_r K^T)^{-1}(K\hat{\rho} - \mathbf{a})$ has approximately a central and non-central χ^2 distribution

$$H_0: Q_n^2 \sim X_g^2(0), \quad H_a: Q_n^2 \sim X_g^2(c) \quad (35)$$

where $c = n\mathbf{a}^T(K\Sigma_r K^T)^{-1}\mathbf{a}$, and $\chi_g^2(c)$ denotes a χ^2 distribution with g degrees of freedom and non-centrality parameter c . Thus, power function for the linear contrast (27) is similarly derived.^[55] As an alternative to the asymptotic results, power function may also be constructed based on the exact sampling distribution of $\hat{\rho}$, i.e., $T_F(\hat{\rho})$. For relatively small sample sizes, such an exact method provides more reliable power estimates, which are useful not only for planning small trials, but also for assessing the accuracy of the asymptotic approach. For example, we have used the exact distribution to evaluate the effect of the surrogacy as well as the normal distribution assumption in our previous investigation and found that the surrogacy assumption has little, while normality has a significant impact on power estimates.^[55] Details on exact distributions and their implementations using Monte Carlo simulations can be found in Ref. [55].

Missing Data Case

As discussed in section “Missing Data Case,” missing data arises frequently in real studies, particularly in longitudinal trials. Within the context of correlation analysis, either X_{it} or Y_{it} or both may be missing. By employing a similar strategy as in regression analysis, we define a vector of binary variables for indicating missing data as follows

$$r_{it} = \begin{cases} 1 & \text{if } (X_{it}, Y_{it}) \\ & \text{is observed} \\ 0 & \text{if } X_{it} \text{ or } Y_{it} \text{ or} \\ & \text{both is missing,} \end{cases} \quad \mathbf{r}_i = (r_{i1}, \dots, r_{im})^\top \quad (36)$$

As before, we again assume no missing data at baseline $t = 1$, i.e., $r_{i1} \equiv 1 (1 \leq i \leq n)$. In addition, we assume MCAR so that r_{it} is stochastically independent of (X_{it}, Y_{it}) .

In the presence of missing data, the Pearson estimates for the observed data can be expressed by using the missing data indicator as follows

$$\hat{\rho}_t = \frac{\sum_{i=1}^n r_{it} (X_{it} - \bar{X}_{\cdot t}) (Y_{it} - \bar{Y}_{\cdot t})}{\sqrt{\sum_{i=1}^n r_{it} (X_{it} - \bar{X}_{\cdot t})^2 \sum_{i=1}^n r_{it} (Y_{it} - \bar{Y}_{\cdot t})^2}} \quad (37)$$

where $\bar{U}_{\cdot t} = (\sum_{i=1}^n r_{it})^{-1} (\sum_{i=1}^n r_{it} U_{it})$. It can be shown that $\hat{\rho} = (\hat{\rho}_1, \dots, \hat{\rho}_m)^\top$ is a consistent estimate of ρ and asymptotically normal.^[56] The asymptotic distribution of $\hat{\rho}$ can be used to construct the power function for testing linear contrasts (27). The asymptotic variance in this case is a function of P_x , P_y , ρ , and the first two moments of $\mathbf{r}_i$. By modeling the moments of $\mathbf{r}_i$ similarly as in section “Modeling Missing Data Indicators with Maskov Processes” for regression models, we can again use the asymptotic distribution to construct the power function for linear contrasts (27).^[56]

ILLUSTRATION

In this section, we illustrate the approaches discussed with two worked examples. Although both examples are motivated by real study designs, we have altered the actual study designs to make them less complex and more suitable for exposition and illustration. Throughout the examples, we set type I error at $\alpha = 0.05$.

Example 1

In a longitudinal trial to compare treatment efficacy of a manualized information-motivation-behavioral skills intervention and a structurally equivalent health promotion control for HIV risk reduction with adolescent girls,^[57] we are interested in estimating power and sample size to detect some hypotheses concerning between-treatment differences at 3 (for short-term efficacy), 6, and 12 months (for long-term efficacy) postbaseline. For illustration purposes, we add a wait-list control, which, unlike the structurally equivalent health promotion, does not offer study participants any health promotion material other than have them assessed at baseline and the three prescheduled follow-up times. With the inclusion of the wait-list condition, we can also assess the placebo effect by the health promotion control.

The appropriate GEE model for this study design is the repeated measures analysis of variance (ANOVA)

$$E(Y_{kit}) = \mu_{ki}, \text{Var}(Y_{kit}) = \sigma_i^2, \quad 1 < i < nk, 1 \leq k \leq g, 1 \leq t \leq m \quad (38)$$

where g indicates the number of groups and n_k the group size. For the current study, $g = 3$ and $m = 4$, with $t = 1$ designating baseline. In addition, assume a common group size n , a common variance σ^2 , and a uniform compound symmetry structure $C_4(\rho)$ for the true correlation of the repeated responses.^[1–53] Under these assumptions, the true variance is given by $V = \sigma^2 C_4(\rho)$.

Now, consider testing for a constant between-group difference over the three postbaseline assessments

$$H_0 = \mu_{ki} - \mu_{(k-1)i} = 0 \quad \text{vs.} \quad H_a: \mu_{ki} - \mu_{(k-1)i} = a, \quad k = 2, 3, 2 \leq t \leq 4 \quad (39)$$

Note that for convenience and illustration purposes, we assumed a constant between-group difference in Eq. (39), though differential between-group changes may be more likely in the real study. In addition, we assumed no between-group difference at baseline so that the hypothesis only involves the means at postbaseline assessments. To eliminate the dependence of the power function on σ^2 , we divided the mean differences in Eq. (39) by σ so that a has the interpretation of the effect size.^[58] To express Eq. (39) in the form of Eq. (3), let

$$K = (\mathbf{c}(1, 2), \mathbf{c}(3, 4), \mathbf{c}(5, 6), -\mathbf{c}(1), -\mathbf{c}(3), -\mathbf{c}(5), -\mathbf{c}(2), -\mathbf{c}(4), -\mathbf{c}(6)), \mathbf{a} = a\mathbf{1}_6) \quad (40)$$

where $\mathbf{c}(i, \dots, j)$ denotes a 6×1 vector with 1 in the rows $i, \dots, j$ and 0 elsewhere, $\mathbf{1}_6$ a 6×1 vector of 1s, and $\beta = \mu$ with $\mu_k = (\mu_{k2}, \mu_{k3}, \mu_{k4})^\top$ and $\mu = (\mu_1^\top, \mu_2^\top, \mu_3^\top)^\top$.

Shown in Fig. 4 are power curves as a function of sample size and within-subject correlation for the hypothesis (39) with $a = 0.15$ under a time-stationary Markov model with a uniform missing data rate $q = 1 - \phi_{11} = 20\%$.

Fig. 4 Power curves for Example 1 with within-subject correlation $\rho = 0.2$ (left plot) and $\rho = 0.8$ (right plot) under (A) no missing data (—), (B) time-stationary Markov model with 20% missing data rate (---), and (C) a trimmed sample with 20% subjects removed (...)

For comparison purposes, we also plotted power based on the full sample and a trimmed sample by removing 20% of the subjects. As noted in section “Missing Data Case,” the trimmed approach is often used to guard against loss of power due to missing data and is justified based on a cross-sectional study design or a longitudinal study with a particular missing data pattern such as the one depicted in Fig. 1.

The plots in Fig. 4 show that the trimmed approach underestimates power with the amount of underestimation depending on the within-subject correlation ρ ; larger ρ leads to bigger differences between the trimmed and Markov model. As ρ measures the strength of correlation between repeated observations, smaller (larger) values of ρ give rise to less (more) correlated responses. Although both approaches have the same expected 20% missing data at each assessment point, they differ on how subjects contribute to the observed data over time. For the Markov model, missing data occurs randomly within each individual over time so that the individuals with observed responses are different across times. In contrast, the trimmed approach is based on a particular, fixed missing data pattern in which the observed responses are from the same subjects over time. Thus, there are more individuals who contribute to observed responses in the Markov model. As a result, this model yields more power than the trimmed approach. In addition, as ρ gets smaller, observations from the same individual become more independent and it matters less whether the observations are from the same individual or different individuals. On the other hand, when ρ gets larger, observations from the same subject become highly correlated, which further decreases the amount of independent information in the trimmed approach. Thus, the difference between the two approaches also varies as an increasing function of the within-subject correlation ρ .

In practice, the amount of missing data typically increases as time elapses, and the uniform missing data rate model is insufficient to capture such a dynamic trend. A one-step Markov model with time-varying transition probability matrices in Eq. (24) provides a way to accommodate a process that generates an increasing amount of missing data over time. Suppose that missing data increases over time at a rate given by

$$E(r_{it}) = p_{11}(1, t) = 0.80 + 0.10(3 - t), \quad 2 \leq t \leq 4 \quad (41)$$

Starting with 10% data missing at time 2, the missing data rate increases by 10% at each next assessment, though the averaged rate over the three assessments is still maintained at 20%. For convenience, we assume that the one-step transition probability to observe a response is independent of the response status at earlier times, i.e., $\phi_{01}(t) = \phi_{11}(t)$ ($2 \leq t \leq 3$). Given Eq. (41), we can use the recursive formula (25) to determine $\Phi(u)$ as well as $\mathbf{P}(1, t)$.

As there is no missing data at $t = 1$, $p_{01}(1, 2) = 0$. It follows that

$$\mathbf{P}(1, 2) = \begin{pmatrix} p_{11}(1, 2), & \bar{p}_{11}(1, 2) \\ p_{01}(1, 2), & \bar{p}_{01}(1, 2) \end{pmatrix} = \begin{pmatrix} 0.9, & 0.1 \\ 0, & 1 \end{pmatrix} = \Phi(1)$$

from which we obtain $\Phi(1)$. Similarly, by setting $t = 3, 4$ in Eq. (25) and solving for $\phi_{11}(u)$, we obtain

$$\Phi(2) = \begin{pmatrix} 0.8, & 0.2 \\ 0.8, & 0.2 \end{pmatrix}, \quad \Phi(3) = \begin{pmatrix} 0.7, & 0.3 \\ 0.7, & 0.3 \end{pmatrix}$$

Shown in Fig. 5 are power curves as a function of sample size for the hypothesis in Eq. (39) with $\mathbf{a} = (0.05, 0.05, 0.1, 0.1, 0.2, 0.2)^\top$ under the one-step time-varying Markov model. As before, we also plotted power based on the full and 20% trimmed sample. Note that unlike the uniform missing data rate model considered earlier, the trimmed sample does not have the same expected missing data rate as the Markov model at each assessment time. However, since the Markov model has an average rate of 20% missing data over the three assessment times, it is still sensible to compare this model with the trimmed approach.

Like Fig. 4, the plots in Fig. 5 also show that the difference between the two approaches varies as a function of the within-subject correlation. However, the trimmed approach no longer consistently underestimates power as in Fig. 4; in fact, it substantially overestimates power when $\rho = 0.8$. This overestimation by the trimmed approach is expected because with the redefined between-group difference vector $\mathbf{a}$, the ad hoc approach has more observations than the Markov model to detect a larger between-group difference at $t = 4$. Thus, with a general missing data process, power results from the trimmed approach become difficult to interpret as the bias can go either direction.

Fig. 5 Power curves for Example 1 with within-subject correlation $\rho = 0.2$ (left plot) and $\rho = 0.8$ (right plot) under (a) no missing data (—), (b) Markov model with time-vary one-step transition probability matrix (---), and (c) 20% trimmed sample (...)

Example 2

In an intervention study on posttraumatic stress disorder, one primary hypothesis is to determine whether the correlation between a biological and psychological measure changes over time. Suppose that there are five assessments; $t = 1, 2, 3, 4, 5$ with $t = 1$ designating baseline. Consider two sets of hypotheses

$$\begin{aligned} H_0 &= \rho_{xy} = (0.5, 0.5, 0.5, 0.5, 0.5)^\top \quad \text{vs.} \\ H_a &= \rho_{xy} = (0.5, 0.75, 0.75, 0.75, 0.75)^\top \\ H_0 &= \rho_{xy} = (0.5, 0.5, 0.5, 0.5, 0.5)^\top, \quad \text{vs.} \\ H_a &= \rho_{xy} = (0.5, 0.55, 0.60, 0.65, 0.750)^\top \end{aligned} \quad (42)$$

where H_a for the first hypothesis implies a constant change over the four assessments postbaseline, while H_a for the second tests for an upward trend from baseline to the last visit.

As in our earlier investigation with no missing data,^[55] we modeled P_x and P_y using a uniform compound symmetry correlation structure, $P_x = C5(\rho_x)$ and $P_y = C5(\rho_y)$, with $\rho_x(\rho_y)$ denoting the constant within-variable X_t (Y_t) correlation. For missing data, we assumed a time-stationary Markov process with a uniform missing data rate ϕ_{11} , as in Example 1.

Shown in Fig. 6 are the power curves (dotted line) for the two hypotheses with $\rho_x = \rho_y = 0.2$. For comparison purposes, we also plotted power based on the full sample (solid line) and a trimmed sample by taking out 80% of the individuals from the original sample (dashed line). The effect of missing data on power is clear from the plots in Fig. 6. In addition, it is interesting to see that the trimmed sample underestimated power as compared to the Markov modeling approach, though the amount of underestimation

Fig. 6 Power curves for the first (left plot) and second set (right plot) of hypothesis in Example 2 with $\rho_x = \rho_y = 0.2$ under (a) no missing data (—), (b) 20% missing data per subject (...), and (c) a trimmed sample with 80% of the original subjects (-----)

Fig. 7 Power curves for the first (left plot) and second set (right plot) of hypothesis in Example 2 with $\rho_x = \rho_y = 0.8$ under (a) no missing data (—), (b) 20% missing data per subject (...), and (c) a trimmed sample with 80% of the original subjects (-----)

is small for both hypotheses. To further explore the impact of the input parameters on power, we changed the values of the within-variable correlation ρ_x (ρ_y), from 0.2 to 0.8, while keeping the other input parameters the same as before. Shown in Fig. 7 are the resulting power curves for the two hypotheses. The plot again shows the impact of missing data on power. However, in comparison to Fig. 6, the power curves now exhibit a different pattern; the power curves of the two missing data samples are no longer close to each other and in addition, the trimmed sample overestimated power for both hypotheses. Thus, as in the regression model case, bias in the power estimates by the trimmed approach can go in either direction.

CONCLUSIONS

In this entry, we reviewed existing work on power analysis for longitudinal and other types of clustered study designs and focused on GEE and LMM for regression analysis and product-moment correlation for correlation analysis. In addition, we also presented our latest development in addressing the issue of missing data pattern. Although various methods have studied the effect of within-cluster correlation within different modeling contexts,^[1,4,29,30,59–61] the effect of missing data pattern has never been systematically examined within the general context of clustered study designs for regression as well as correlation analyses. Thus, this new development represents a major advance in research on power analysis for sample size calculation (68).

Our investigation of power as a function of the within-subject correlation in the presence of missing data

indicates that power is highly dependent on this parameter whether conducting regression or correlation analyses. This interplay between within-subject correlation and missing data illustrates the importance to address the issue of missing data pattern to provide reliable power estimates for real study designs. In studying the effect of random missing data patterns on power, we contrasted the proposed approaches with a widely used ad hoc method that accounts for missing data by inflating the sample size calculated based on a particular fixed missing data pattern. As illustrated by the examples in section “Illustration,” this trimmed approach in general provides unreliable estimates as bias in the power estimates by this approach can go either direction. Although other existing ad hoc methods may provide less biased estimates, they are more model specific and inapplicable to the general models considered in this entry.

One limitation of the work proposed to address missing data is the MCAR assumption. Accommodating more general missing data assumptions such as the missing at random (MAR) mechanism not only requires more complex models for the missing data indicator, but also different types of parameter estimates. For example, under MAR, the estimating equations considered in section “Part I. Power Analysis for Regression Models” no longer yield consistent estimates, and different type of estimating equations must be considered.^[35,37,62–67] We will address these more general missing data mechanisms in future research.

ACKNOWLEDGMENT

This research is supported in part by an NIH/NIDA R01-DA012249 grant (Feng, Tang, and Tu) and by an NIH/NIAD grant K22AI 51186 (Kowalski). We thank Prof. Chow at Duke University for inviting us to write this paper and for Associate Editor, Alison Cohen, for the Encyclopedia of Biopharmaceutical Statistics (EBS) and Cheryl Bliss-Clark, in the Department of Biostatistics and Computational Biology at University of Rochester, for assistance with manuscript preparation.

Minor updates have been made by the Editor-in-Chief in order to reflect developments since publication of the *Encyclopedia of Biopharmaceutical Statistics, Third Edition*.

Abstract

Companion diagnostics have become important medical devices for tailoring treatment choices to individual patient characteristics. A companion diagnostic test is one that is essential for the safe and effective use of a therapeutic product. Companion biomarker tests measure or detect one or more biomarkers. We review statistical methods for evaluating companion diagnostics at different phases of development, including biomarker development, analytical validation, and clinical validation.

Keywords: Biomarker discovery; Biomarker strategy; Clinical utility; Enrichment; Omics-based classifier; Predictive biomarker.

I. INTRODUCTION

Companion diagnostic tests have become increasingly important to the advancement of precision medicine, i.e., personalizing or tailoring medical treatment or management decisions based on individual patient characteristics. The US Food and Drug Administration (FDA) defines an *in vitro* companion diagnostic device (or test) as one that is essential for the safe and effective use of a therapeutic product^[1]. The therapeutic product may be drug, biologic, novel product, or existing product with a new indication.

In their initial guidance on companion diagnostics^[1], FDA indicates that an *in vitro* diagnostic test could be essential for the safe and effective use of a therapeutic product if it is used to

- identify patients who are most likely to benefit from the therapeutic product,
- identify patients likely to be at increased risk for serious adverse reactions as a result of treatment with the therapeutic product,
- monitor response to treatment with the therapeutic product for the purpose of adjusting treatment (e.g., schedule, dose, discontinuation) to achieve improved safety or effectiveness,
- identify patients in the population for whom the therapeutic product has been adequately studied, and found safe and effective, i.e., there is insufficient information about the safety and effectiveness of the therapeutic product in any other population.

In a second, draft guidance^[2], FDA elaborates on principles for co-development of an *in vitro* companion diagnostic test with a therapeutic product, including regulatory processes and scientific principles to support contemporaneous marketing authorization of the companion diagnostic with the corresponding therapeutic. Topics covered by the guidance include analytical validation of the test (demonstration that the detection or measurement of analyte(s) by the test is accurate and reliable), clinical validation of the test with a prospective or retrospective study, and types of marketing claims supported by validation studies. Statistical principles are also covered, including clinical study designs and robustness of study conclusions to missing test results.

A companion diagnostic assay is usually based on detection or measurement of one or more biomarkers. The biomarkers may be directly related to the pharmacodynamic or pharmacokinetic properties of the corresponding therapy^[3]. In other instances, efforts are undertaken to discover one or more biomarkers empirically to develop a biomarker-based classifier or signature that can explain heterogeneity in a treatment effect.

Much but not all of the literature on companion diagnostics concerns oncology because of opportunities to develop highly effective cancer treatments for molecular targets that can be evaluated with biomarker measurements. In oncology, predictive biomarkers are defined as informing on likely outcomes with specific treatments (e.g., relative sensitivity or resistance), while prognostic biomarkers are defined as informing on likely outcomes independent of specific treatment (i.e. ability of tumor to proliferate, invade, and/or spread)^[4]. In general predictive

markers are candidates for the development of companion diagnostic tests, while prognostic markers may not be, although they could be clinically actionable. Well-known examples of prognostic signatures are Oncotype DX and MammaPrint for patients with stage I, estrogen receptor positive breast cancer^[5,6]

A large literature exists on principles for discovery and validation of biomarkers for treatment decision making. Guidelines are available regarding design, conduct, analysis, and reporting of clinical trials of a therapeutic in combination with a companion diagnostic test for treatment selection. Guidelines developed by researchers and professional medical societies include Deverka, Messner, et al.^[7], McShane, Cavenagh, et al.^[8], Fridlyand, Simon, et al.^[9], Matcher^[10], Micheel, Nass, et al.^[11], Moons, Kengne et al.^[12], Moore^[13], Khleif, Doroshow, et al.^[14], Ransohoff and Gourlay^[15], Simon, Paik, et al.^[16], Pepe, Feng, et al.^[17], Simon^[18], McShane, Altman, et al.^[19], and Bossuyt, Johannes, et al.^[20]. In addition, FDA and the National Institutes of Health (NIH) have jointly published a glossary on biomarkers, endpoints, and other tools (BEST)^[21].

In this entry, we review statistical methods for companion diagnostic tests. In lieu of the regulatory term, these tests have been called predictive marker tests and treatment selection tests in the literature. Our intention is to review developments that we consider important, not to convey FDA's current thinking on accepted statistical practices for companion diagnostics.

In Section II we briefly review statistical methods and principles in biomarker discovery and signature development. In Section III, we review different types of evaluations that may be required for validating companion diagnostic tests. In Section IV we review clinical study designs for validating a companion diagnostic test with its corresponding therapeutic product. In Section V we discuss selected statistical methods for evaluating the clinical utility of a companion diagnostic. In Section VI we consider missing test results as well as other types of non-missing test results that require special care in statistical analysis. In Section VII, we discuss follow-on companion diagnostics tests. Finally, in Section VIII we provide some concluding remarks.

II. BIOMARKER DISCOVERY AND SIGNATURE DEVELOPMENT

A strength of some emerging technologies is that a very large number of biomarkers can be interrogated simultaneously. For example, next generation sequencing of the whole genome can potentially evaluate 3.2 billion base-pairs of DNA in one sample. However, despite intense biomarker discovery efforts made possible with emerging technologies, relatively few biomarkers have been commercially developed into marketable tests for treatment decision making^[22]. Indeed, no complex classification signature

combining multiple biomarkers has been FDA-approved as a companion diagnostic^[23], despite that methodologies for classifier development abound, e.g., Fisher linear discriminant analysis, maximum likelihood discriminant rules, nearest-neighbor classifiers, classification trees including classification and regression trees (CART), aggregation classifiers including bagging and boosting, support vector machines (SVMs), random forests, Naïve Bayes classifiers and many more^[23–25].

While thousands of biomarkers may be simultaneously evaluated as candidate predictors of treatment efficacy or safety, typically most are uninformative for a clinical outcome, complicating efforts to identify signal from noise. Accompanying the simultaneous evaluation of a large number of candidate biomarkers is large random variability, which can easily generate spurious associations of biomarker values with clinical conditions of interest. To mitigate the large multiplicity problem, statistical methods have been used to control the false discovery rate.

In omics-based discovery research, a small sample size n is frequently used to evaluate a much larger number of candidate biomarkers p . In this small n large p setting, if the p variables are not co-linear they are typically capable of being used to develop a rule that classifies disease state correctly in all n patients with no prediction error. However, the development and evaluation of a classifier on the same dataset amounts to “double-dipping”, which can lead to large internal bias in the performance of the classifier, known as resubstitution bias^[27–29].

To increase confidence that a classification model can predict a clinical condition in out-of-sample testing, its performance may be cross-validated within a developmental dataset. In split-sample cross-validation, one part of a dataset is used to build the model and the remaining part is used to test it. If model building is automated, the data may be split repeatedly to train and test the model. Commonly, the classifier is developed on $k - 1$ parts and tested on the remaining k th part, with the process repeated k times for each possible selection of $k - 1$ parts for training. Performance is summarized (e.g., averaged) across the k test sets. As k increases, average performance across the test sets becomes less biased but more variable. In leave-one-out cross validation, $k = n$, and average performance is least biased but most variable. Alternatively, in one form of bootstrap cross-validation, a bootstrap dataset of the same size as the original dataset serves as the training dataset and units left out of the bootstrap dataset serve as the test dataset.

A critical step in developing a classifier is feature selection, that is, selection of the variables (e.g., biomarkers) used in the classifier as predictors for the clinical condition of interest. Feature selection is typically the largest source of bias in resubstitution performance and in cross-validation performance if it is not considered to be a model-building step^[27–28]. A common mistake is to select features based on an entire dataset and cross-validate only the steps used to build a model with the selected features.

As with all phases of medical product development, biomarker discovery is more likely to be successful to the extent that it is planned. Major discoveries that advance the field are often surprises (almost by definition), but are usually the result of carefully planned, reproducible research. Principles of experimental design are often crucial to employ in early phase studies^[30] to avoid generating biomarker associations with clinical conditions that are confounded by, for example, convenience sampling, sample test order, co-morbidities, analyte instability during collection/storage, variation in sample handling/processing, batch effects, geography, ethnicity, etc.

III. LEVELS OF DIAGNOSTIC TEST EVALUATION

Fryback and Thornbury^[31] organized the evaluation of diagnostics devices (tests) into six levels: technical efficacy, diagnostic accuracy efficacy, diagnostic thinking efficacy, therapeutic efficacy, patient outcome efficacy and societal efficacy. While they developed their conceptual model with a focus on diagnostic imaging systems, it is broadly applicable to the evaluation of any diagnostic test, in particular companion diagnostics. Commonly, diagnostic tests are evaluated for technical efficacy (measurement quality) and diagnostic accuracy (association of test result with a clinical condition of interest).

For in vitro diagnostics, technical efficacy (level 1) corresponds to analytical performance, the characterization of the test to detect or measure analytes accurately and reliably. Generally, in vitro diagnostics (IVDs) are analytically validated prior to clinical validation^[5]. To demonstrate analytical validity, studies are designed to evaluate various aspects of test measurement quality, which may include bias, precision, limit of detection, reagent stability, analytical specificity, and, when processed samples are used in place of clinical samples, commutability between sample types. Bias is evaluated by comparing a test measurement with the true (or accepted reference) value of the measurand. Measurement imprecision (variability) can be evaluated with replicate measurements taken under the same set of conditions, e.g., within a run (repeatability) or under different conditions, e.g., replicates tested in different labs (reproducibility). Reagent stability may refer to shelf-life, in-use life, or shipment. Analytical specificity refers to robustness of the measurement to interfering substances, cross-reactivity, or cross-contamination.

The Clinical Laboratory Standards Institute (CLSI) develops guidelines on clinical and laboratory practices, including protocols for evaluating various aspects of the analytical performance of laboratory measurement procedures. Evaluation Protocol guidelines include an overview of evaluations of analytical performance that may be necessary to perform for a measurement procedure^[32] and a harmonization of symbology and equations used to describe statistical equations and models in the guidelines^[33].

For many diagnostic tests, the focus of clinical evaluation is diagnostic accuracy – level 2 in the Fryback-Thornbury hierarchy – using such measures as sensitivity, specificity, diagnostic likelihood ratio, predictive value, and receiver operating characteristic (ROC) plot. In contrast, because companion diagnostics are associated directly with treatment recommendations, clinical evaluation is typically based on therapeutic and patient outcome efficacy (levels 3–4). Therapeutic efficacy refers to the frequency with which the diagnostic result helped the physician plan the management or treatment of the patient. Patient outcome efficacy – also called clinical or medical utility in literature – refers to the effect of the test on patient outcomes when used as intended.

IV. CLINICAL TRIAL DESIGNS

Many companion diagnostic tests provide a binary output (test negative or positive) to identify a population most likely to benefit from a therapeutic product. Other binary tests identify a population at risk for a serious adverse event if treated with the product. The tests may be based on measurements of one or more biomarkers that are thought to be predictive of these endpoints. For binary-valued companion biomarker tests that determine eligibility of treatment, three prospective Phase III trial designs are the biomarker-stratified (or interaction) design, the biomarker-strategy design, and the enrichment (or targeted) design (Fig. 1)^[34–35]. The designs could be generalized to evaluate companion diagnostic tests that discriminate among multiple treatment options.

A. Biomarker-Stratified Design

In a biomarker-stratified design, all patients are enrolled regardless of biomarker test value. Enrolled patients are randomized to the treatment or a control. The treatment effect (e.g., hazard ratio between treatment and control) is stratified by biomarker test value. If test value explains variation in treatment effect that is statistically and clinically significant, then the test could be considered essential for the safe and effective use of the treatment and therefore a companion diagnostic (Section V). For example, for a test to be considered a companion diagnostic, the treatment effect may need to be positive (beneficial) and large (clinically significant) in patients who are biomarker test positive, but close to zero or negative (harmful) in patients who are biomarker test negative.

For small to moderately sized trials, imbalances may occur by chance in the numbers of patients randomly assigned to the treatment and control groups within subsets defined by biomarker test value. The imbalance can lead to less precision in the treatment effect estimate relative to 1:1 perfect balance in treatment assignment. Stratification of the randomization by biomarker test value would ensure 1:1 balance and thus may increase precision of estimation, but is not necessary for unbiased evaluation of the treatment

Fig. 1 Clinical Trial Designs for Treatments with Companion Diagnostics

effect within biomarker subsets because within the subsets treatment assignment is randomly generated^[36]. In general, the treatment effect within a biomarker subset is usually better estimated if adjusted for covariates observed to have effects on outcome and distributed differently between the treatment and control groups.

B. Enrichment Design

In an enrichment design, only patients with particular biomarker test values are enrolled into a trial of the investigational treatment. For example, in a predictive enrichment strategy^[37], the only patients enrolled are those with a biomarker test value indicating they are more likely to respond to treatment. The enrichment design requires that the test be available during enrollment to screen patients for inclusion into the trial depending on their biomarker test value.

An enrichment design may be necessary for a clinical trial to have equipoise in randomizing patients to a treatment or a control. While the biomarker-stratified design is efficient for evaluating differential treatment effects in biomarker subpopulations, its assignment of the treatment to some patients with biomarker test values that are supposed to predict lack of benefit or increased risk of an adverse event could be unethical. In general, if the predictive ability of the biomarker for an efficacy or safety outcome during treatment is based on a strong biological rationale or compelling Phase II evidence, and if the biomarker is measured well by the test (i.e., is accurate and reproducible), then clinical equipoise for a randomized trial of the treatment may only exist among the subset of

patients with biomarker test values that predict a favorable benefit-risk trade-off for the treatment.

An enrichment trial may show that the treatment is safe and effective in a population defined by biomarker test value. The enrichment trial is not designed to evaluate if the treatment is safe and effective in other populations. For example, an enrichment trial may demonstrate that the treatment effect is clinically and statistically significant in patients who are biomarker test positive. The test would then be indicated as a companion diagnostic to select biomarker test positive patients as the intended use population for the treatment. However, the treatment may also happen to be effective in biomarker test negative patients. In practice, these patients may be dissuaded from receiving the treatment and obtaining its benefits.

C. Biomarker Strategy Design

In a biomarker strategy design, patients are randomized to either have their biomarker test value used or not used to determine if they should receive the experimental treatment or the control^[40]. If the biomarker value is not used, the patient receives the control. If the biomarker test value is used, then a patient receives the treatment if they test positive for the biomarker and the control if they test negative. The design is an attempt to evaluate if test-guided treatment selection can improve average clinical outcome. However, as noted by many authors^[35,39–41], the design has at least two shortcomings

First, the effectiveness of the test-based strategy for selecting the treatment cannot be separated from a

homogenous treatment effect. In this case, even a random test will select a subset of patients for whom the treatment is effective relative to control. Similarly, if the treatment is effective in subgroups unrelated to the test strategy, then even a random test strategy will by chance select some patients in these subgroups. In both cases, the study will tend to show that outcomes are better in the test strategy arm than the control arm. These results may be over-interpreted to mean that the test is appropriately selecting patients for treatment when in fact it is selecting patients at random. To avoid over-interpretation of study results, a difference between the test strategy and control arm in an outcome would be compared with its null distribution if the test strategy was random. Unfortunately general methods for determining this null distribution are unclear.

Second, the biomarker strategy design is inefficient. Patients who are biomarker test negative will receive the control whether they are randomized to the test strategy arm or the control arm. These patients will dilute the average difference between the test strategy arm and the control arm in an outcome. More precisely, if a linear treatment effect on outcome equals Δ in biomarker test positive patients and the probability of testing positive is π , then the expected difference between the test strategy arm and the control arm is $\pi \Delta$. Consider that the sample size to power a study to detect a treatment effect is roughly inversely proportional to the square of the effect size. Then, the sample size would need to be $1/\pi^2$ times greater for the biomarker-strategy design than for an enrichment design in which only biomarker test positive patients are enrolled^[40–41]. For example if $\pi = 0.5$, the sample size would need to be 4 times larger for the marker strategy design than the enrichment design to detect the linear effect.

D. Prospective-Retrospective Design

In a so-called prospective-retrospective study, a prospective plan is developed for evaluating an existing randomized trial for a treatment and its companion diagnostic test. The existing trial would ideally enroll the same patient population and have the same objectives as the prospective-retrospective study. Uniform policies should be in place for sample collection, handling, and processing. The test would need to be analytically validated for stored samples^[16]. An adequate amount of sample material would need to be available for testing from enough patients in the trial for test results to be representative.

The biomarker-stratified design is often accomplished with retrospective study of a trial that was conducted prior to knowing that treatment efficacy or safety could have been predicted by a biomarker test. The retrospective study permits evaluation of the predictive ability of the biomarker test by examining the study for biomarker by treatment interaction on relevant outcomes.

A prospective-retrospective study has the potential to expedite validation of a companion diagnostic test for a

therapeutic. However, qualitatively, the level of evidence for a prospective-retrospective study is considered lower than for a prospective randomized clinical trial for several reasons, including the retrospective analysis is based on a clinical trial usually not explicitly designed for the retrospective analysis objective, is based on test results on available stored samples rather than on fresh samples, and could be subject to confounding due to uncontrollable factors^[16]. Therefore, a recommendation is that validation of a companion diagnostic test be based on more than one prospective-retrospective study yielding similar conclusions^[16].

E. Other Designs

Other fixed sample size designs for randomized trials of treatments in combination with biomarker tests have been described and evaluated^[34,38–42]. A variant on the enrichment design is to enroll only the subset of patients for whom biomarker test result changes the treatment decision from the pre-test planned therapy (i.e., the subset with level 4 therapeutic efficacy in Fryback and Thornbury's hierarchy). For example, to evaluate the clinical utility of procalcitonin to guide antibiotic therapy decision making for patients suspected to have lower respiratory tract infection, patients with a low procalcitonin level who would otherwise have been started on a course of antibiotic therapy could be randomized to receive the therapy or not, the general premise of the upcoming TRAP trial (<http://arlg.org/studies-in-progress>).

Some trials of treatments with companion biomarker tests are designed to be adaptive in various aspects, including sample size, enrollment (enrichment), randomization ratio, biomarker signature, and biomarker threshold (e.g.,^[43–48]). An adaptive threshold design is a special type of a biomarker analysis design^[47] for adaptive determination of a biomarker-based subset in whom a treatment is recommended. Adaptive designs that develop and validate a companion diagnostic in the same study blur the usual recommendation to perform these phases on separate datasets. However, a biomarker analysis design could be conceivable for the pivotal validation of a companion diagnostic with exceptional and highly robust analytical accuracy and reproducibility.

Basket and umbrella study designs are being used to increase clinical trial efficiency for evaluating therapies in oncology with molecular targets.^[44,49] In a basket trial, cancer patients are screened with a biomarker test for the molecular target of an investigational therapy, permitting its evaluation in multiple histological subtypes or tumor types (the basket). In an umbrella trial, a central infrastructure is used to conduct multiple enrichment subtrials of molecularly targeted drugs with companion diagnostics, with a study design that usually permits flexibility to add, drop or modify subtrials as evidence from the trial accumulates or emerges elsewhere.

V. CLINICAL EVALUATION OF COMPANION DIAGNOSTICS

A. Treatment by Biomarker Interaction

In the biomarker stratified design, an observed statistically significant interaction between treatment and biomarker on an outcome can be supportive of the biomarker test being clinically useful as a companion diagnostic, but by itself may be insufficient. Examples can be constructed where the same level of interaction can arise for a biomarker that is clearly useful for treatment decision making and for another biomarker that is clearly not^[50–52].

B. Time-to-Event Analysis

When the outcome is time to an event such as progression or death, Kaplan-Meier plots may be used to compare biomarker test negative and test positive subsets on the difference between treatment and control groups in risk of the event at specified follow-up times. For a biomarker test providing a quantitative measurement or continuous score value, the overall utility of the test as a companion to a treatment may be assessed by comparing treatment and control groups on the predictiveness curve, a plot of risk as a function of quantile in biomarker test value^[37].

C. Overall and Biomarker Subset Analyses

In biomarker-stratified trials, biomarker test positive patients are typically anticipated to be more likely to receive benefit from the treatment. However, the treatment effect may be of interest in the overall study population as well as in subsets defined by the biomarker test. A statistically significant treatment effect overall may be homogeneous across the biomarker-defined subsets or may be driven by a large treatment effect in the biomarker test positive subset S . In the latter situation, common sense would indicate that the treatment should not necessarily be given to everyone despite the overall treatment effect being statistically significant^[53].

To determine if a treatment should be given overall or just to a biomarker defined subset, Freidlin et al.^[54] propose a marker sequential test (MaST) procedure. The procedure consists of testing null hypotheses H_O for treatment effect in the overall study population O , H_S for treatment effect in biomarker test positive subset S , and $H_{S'}$ for treatment effect in biomarker negative subset $S' = O - S$, controlling the overall type 1 error rate at significance level α among these three hypotheses (Fig. 2). First, H_S is tested at level $\alpha_S < \alpha$. If H_S is rejected, then α_S is reused to test $H_{S'}$ at full level α . If H_S and $H_{S'}$ are both rejected, then the MaST procedure says the treatment can be given to everyone. If $H_{S'}$ is not rejected, then the MaST procedure says the treatment is indicated only for biomarker test positive subset S with the biomarker test indicated as a companion diagnostic for

O: overall population; S: test positive subset; S': test negative subset

If H_S rejected at α_S ,
then claim for subset S is met;

If $H_{S'}$ also rejected at α , overall claim met.
else if H_O rejected at $\alpha - \alpha_S$, overall claim met.

Fig. 2 Marker sequential test (MaST) procedure^[54]

selecting this subset for treatment. If H_S is not rejected, then H_O is tested at level $\alpha - \alpha_S$ as a Bonferroni correction for multiple testing. If H_O is rejected, then the MaST procedure says the treatment can be given to everyone.

D. Impact of Biomarker Analytical Accuracy on Clinical Performance

The analytical accuracy of a companion diagnostic can be used to inform on its capacity to predict treatment response. For example, the performance of the absence or presence of a biomarker $S = 0, 1$ to predict non-response or response $R = 0, 1$ to a treatment can be defined as

$$\delta = p_1 - p_0,$$

the difference in probability of response $p_s = \Pr(R = 1 | S = s)$ between patients with the biomarker ($S = 1$) and those without it ($S = 0$). Suppose an imperfect test is used to obtain the biomarker status as $S^* = 0, 1$ and its predictive values for the biomarker are $\pi_t = \Pr(S = 1 | S^* = t)$, $t = 0, 1$. Assume that any measurement error by the test is *non-differential* to response status, that is, $S^* | S, R = S^* | S$. Equivalently, $R | S, S^* = R | S$, i.e., given the true biomarker status, the test is non-informative for response. Then the performance of the test to predict response is

$$\delta^* = \delta a,$$

the performance δ of the biomarker attenuated by the factor

$$a = \pi_1 - \pi_0 = PPV + NPV - 1$$

where $PPV = \pi_1$ and $NPV = 1 - \pi_0$ are the positive and negative predictive values of the test^[55].

E. Causal Effect Estimands

The causal effect of a treatment within a biomarker-defined subset is considered fundamental to evaluating a biomarker test as a companion diagnostic to the treatment^[56–60].

Causal effects require consideration of the counterfactual outcome that would have occurred if a patient on treatment had instead been on control (or vice versa). Fortunately, in randomized trials, potential outcomes are independent of treatment assignment, permitting causal treatment effects to be estimated from the observed data alone^[61–62].

To evaluate a biomarker test, Simon^[60] proposes causal estimands for sensitivity, specificity, and predictive value. The positive predictive value (PPV) is the probability that time to event is longer for a test positive patient on treatment than if she were on control. The negative predictive value (NPV) is the probability that time to event is longer for a test negative patient on control than on treatment. Under assumptions permitting causal effect estimation, Simon derives estimands of these quantities as simple functions of proportional hazard ratios for biomarker test negative and positive patients and also for other non-proportional hazards models. Applying Bayes Theorem to the predictive values, true and false positive fractions (sensitivity, $1 - \text{specificity}$) can be derived as the probability of testing positive for the biomarker given time to event is, respectively, longer or shorter on treatment than on control.

F. Bayesian Methods

Because of their ability to draw inferences from complicated study designs and on complicated estimands, Bayesian methods can be useful for evaluating biomarker-defined subsets as companion diagnostics^[46,63–64]. Lunceford^[63] uses Bayesian methods to correct for disproportionate enrichment of the biomarker subset by viewing it as a missing data problem. Schnell et al.^[64] use Bayesian methods to determine a pair of credible subgroups in whom the probability of the individualized treatment effect being clinically significant is large or small, respectively.

G. General Considerations

Practical considerations have been proposed for deciding when a treatment should be given to everyone or to just a biomarker-defined subset based on a biomarker-stratified, all-comers trial^[51–52,65]. Broadly applicable statistical procedures for developing, calibrating, evaluating and comparing marker-guided treatment decision rules have been developed^[66]. Many other contributions, not cited here, have been made to the statistical evaluation of predictive biomarker tests.

VI. MISSING TEST RESULTS

For trials of treatments with companion diagnostic tests, test results may be missing in some patients. A sample may be unavailable or unevaluable. A patient may not have given consent to test their sample. The missing data mechanism is simplified if a sample is taken and consent is given to

test the sample prior to treatment assignment^[36]. With this design, the probability of a missing test value is independent of treatment assignment, increasing confidence that the observed treatment effect in the trial is internally valid among samples with non-missing test results.

Test results may be uninterpretable or equivocal. An uninterpretable test value may be considered not as missing but as a separate category of test result unless in practice the test will be repeated until a valid test result is obtained^[67]. An equivocal test result is a non-missing test value that is neither negative nor positive and therefore by design is a separate category of test result. Equivocal test results are sometimes called indeterminate.

When meaningful for analysis, imputation of missing test results can simplify likelihood-based inferences and increase generalizability compared with inferences based on patients with complete data. If test results are assumed to be missing at random, they may be imputed based on variables that could affect the test result. Variables that are most predictive of the missing test result are not necessarily patient and disease characteristics or even outcome, but characteristics of the sample, its handling, and its processing. Robustness of inferences to missing test data can be considered in a sensitivity or tipping point analysis^[68].

In retrospective studies, samples are archived and not tested until later with the companion diagnostic test. Archiving may affect the test result. A test result that is valid on a fresh sample may become invalid, uninterpretable or experience drift after the sample is stored for a period of time. If a test is to be applied to stored samples, analytical validity of the test on stored samples is important to characterize.

For many reasons the distribution of available test results on archived samples may be distorted relative to the distribution in fresh samples (e.g., tumors with larger volume may be overrepresented). This distortion may limit the generalizability of treatment effects observed in retrospective studies of archived samples.

In many co-development programs of a therapy and its companion diagnostic (CDx), an enrichment trial for the therapy is conducted before the CDx is ready. Because the CDx is unavailable, a clinical trial assay (CTA) is used to screen patients for the trial. The CTA and CDx are usually based on the same technology, but nonetheless can be discordant for some patients. To “bridge” the results of the trial from the CTA to the CDx, samples are saved for re-testing by the CDx when it becomes available. For samples that are unavailable or unevaluable in re-testing, the CDx test result is missing. For patients who are CDx positive but not enrolled into the trial because they were CTA negative, outcome data are missing. Performance goals and estimation strategies for bridging studies have been proposed^[69–70]. In one approach, if variation between the CTA and CDx is similar to variation within the CTA in repeated testing of the same subject, then the two tests could be considered interchangeable and expected to perform similarly.

VII. FOLLOW-ON COMPANION DIAGNOSTIC TESTS

After the first companion diagnostic for a treatment has been validated and granted marketing approval (by the US FDA or another regulatory agency), other companion diagnostics may be developed for the same indication. Unfortunately, a randomized clinical trial for a follow-on companion diagnostic may not be possible to conduct. Clinical equipoise is generally not present to randomize patients to the treatment or a control therapy because the approved companion diagnostic already indicates whether the patient should or should not receive the treatment.

In an attempt to infer whether a follow-on companion diagnostic will have clinical performance similar to an approved companion diagnostic for the same indication, the follow-on may be evaluated for concordance with the approved companion diagnostic^[71]. If the follow-on and the approved test have results that are concordant in a very high proportion of patient samples, then clinical performance for the follow-on could be expected to be similar to the approved test. The appropriateness of such a conclusion hinges upon the assumption that concordance study samples and patients are transportable to the clinical trial in which the approved test was evaluated.

Ideally, a concordance study of the follow-on with the approved companion diagnostic is conducted on samples from the randomized trial in which the approved companion diagnostic was evaluated. The clinical samples could be re-tested with the follow-on provided archiving of the samples is not detrimental to the quality of the follow-on test result. For biomarker-stratified all-comers trials, re-testing of the clinical samples would permit evaluation of clinical efficacy of the follow-on. For enrichment trials, re-testing with the follow-on may be conducted on all screened samples. However, only patients enrolled into the trial, i.e., those with a sample that passed the appropriate enrichment criterion (e.g., biomarker positive according to the approved test) would have clinical outcome information on which to evaluate clinical efficacy of the follow-on re-test result.

VIII. CONCLUSION

For many diagnostic tests, clinical validation consists of evaluating the association of the diagnostic test result with a current or future health condition in an observational study of diagnostic accuracy. In contrast, a companion diagnostic is typically evaluated for clinical utility in a randomized clinical trial of the corresponding therapeutic. Companion diagnostics have direct clinical consequences because they are intended for the safe and effective use of a corresponding therapeutic product. In the foreseeable future, companion diagnostics will continue to be crucial

for individualized safe and effective treatment of cancer and other diseases in efforts to improve health care through precision medicine.

Comparability Studies: Statistical Considerations

Jason J.Z. Liao

Merck & Co., Inc., North Wales, Pennsylvania, U.S.A.

Li He and Robert Capen

Merck & Co., Inc., West Point, Pennsylvania, U.S.A.

Abstract

The purpose of this entry is to describe some statistical approaches that might be considered when designing and analyzing comparability studies for biological products or processes. In its most basic form, a comparability study seeks to compare a “test product” to a “reference product.” This is accomplished through evaluation of the extensive data obtained on both the test and reference products from analytical and biological assays as well as from nonclinical and clinical testing. To conclude two products or processes are comparable it is first necessary to define a standard for demonstrating comparability. Without a precise, quantitative definition that is accepted by regulatory authorities and the scientific community, it is impossible to prove conclusively that two products (or processes) are indeed comparable. But defining such a standard is not straightforward and often relies on expert opinion that, ideally, is driven by quality considerations, regulatory guidance and clinical safety or efficacy concerns. The usual bioequivalence approach that is appropriate for generics is not acceptable for biological products or processes due to their complexity. Regulatory guidance recommends following a step-wise approach utilizing a totality-of-evidence strategy, which requires collaboration among the pertinent experts, including statisticians. The demonstration of comparability does not necessarily imply that the test and reference products are identical but does ensure that any difference or change between them is not considered scientifically or clinically relevant.

Keywords: Clinical endpoint; Critical quality attribute; Equivalence margin; Equivalence testing; PK/PD; Plausibility interval; Prediction interval; Quality range; Tolerance interval; Totality-of-evidence.

INTRODUCTION

A comparability study is simply a study that seeks to compare two or more things. For example, a process modification is made and the post-change process is compared to the pre-change process, a replacement analytical method is validated and compared to the existing method, a new drug product image is developed and compared to a previously filed image, a biosimilar product is produced and compared to the reference product, etc. Each of these involves a comparison of a “test product” (post-manufacturing change, replacement assay, new image, biosimilar) to the “reference product” (pre-manufacturing change, existing assay, filed image, innovator). In this entry, “comparability” is defined in a broad sense to mean “(bio)similarity”, “bridging”, “equivalence”, etc. The demonstration of comparability does not necessarily mean that the quality attributes and other key parameters of interest of the reference and test product are identical, but that they are highly similar and that the existing knowledge is sufficiently predictive to ensure that any differences in quality attributes and the key parameters of interest have no adverse impact upon safety or efficacy

of the drug product. Determination of comparability can be based solely on quality considerations if the manufacturer can provide sufficient assurance of comparability through analytical studies related to quality attributes. Additional evidence from nonclinical or clinical studies is considered appropriate and required when quality data are insufficient to establish comparability.

Improvements are commonly applied to biological products in production methods, process and control test methods for product characterization, or changes in equipment or facilities both during development and after approval. There are three major reasons that a biological product manufacturer may seek to make changes to an existing process or product:

- **Competitiveness.** Improving product quality, yield, and stability as well as increasing manufacturing scale and enhancing customer experience helps the manufacturer maintain a competitive advantage.
- **Innovation.** Enhancements in manufacturing processes and test methods bring important and improved products to the market more efficiently and rapidly.

- Compliance. Regulatory agencies acknowledge that product and process changes are necessary for the biotechnology industry to advance. A manufacturer must stay in compliance as regulatory requirements evolve.

Similar biological products (“biosimilars”) may help reduce health care costs and increase accessibility to patients. A biosimilar is not an identical or “generic” copy of the reference product. It is, however, highly similar to the reference product, notwithstanding minor differences in clinically inactive components. To develop a biosimilar, a manufacturer may need to create a totally new process. It can even take highly experienced companies many years to devise the technologies necessary to cultivate and genetically engineer the living cells that produce the proteins and antibodies that are filtered and refined into successful biological drugs. Regardless of whether an existing process is updated or a new process is created for the purpose of developing a biosimilar, it is a regulatory requirement for the sponsor to demonstrate comparability between the test and reference products.

The purpose of this entry is to describe some statistical approaches that might be considered when designing and analyzing both analytical and clinical studies to compare a test product to a reference product. Ideally a comparability study would require data to be collected proactively through a designed experiment. When that is not feasible, historical data can be collected and evaluated instead. For example, only historical data are likely to be available on batches tested prior to making a change in the manufacturing process. The nature of the comparison depends on the relevance of the attribute being studied as well the type of data generated. On one extreme, a clinical study requires pre-specification of a number of important characteristics, including, sample size, power, confidence level, acceptance criteria, randomization plan, etc. in conjunction with a formal statistical test of hypothesis or equivalence. On the other extreme, for some analytical attributes a graphical comparison of chromatograms generated on some of the reference and test batches might be all that is required. Regulatory guidance recommends following a step-wise approach for demonstrating comparability using data obtained from analytical and biological assays as well as from nonclinical and clinical testing based on a totality of evidence strategy. But how exactly is comparability demonstrated? Without a clear, objective and scientifically relevant definition of what it means to be “comparable,” there is no way to prove conclusively that two products or processes are indeed comparable. In 1992 the FDA adopted the “80–125%” standard for clinical testing that is still applied today, namely, the 90% confidence interval for the ratio of bioavailability measures must fall entirely within 80%–125%. No such standard exists for non-clinical testing. Simply translating the clinical standard into a non-clinical setting (e.g., bioassay testing) is not a practical solution. This may seem obvious but it is nevertheless a point worth stating.

This entry is divided into two general categories: Analytical and Clinical. While the discussion focuses primarily on statistical aspects, Statistics is just one component of the overall evaluation strategy. Input is also required from other key areas including regulatory, quality, CMC, etc. Data from animal studies and pre-clinical potency testing may also be necessary to assess comparability completely but will not be discussed. An overall summary that also includes some notions on how a biologics manufacturer might objectively implement a “totality of evidence” strategy is provided in the Conclusions section.

EVALUATING THE ANALYTICAL COMPARABILITY OF A BIOLOGICAL PRODUCT

General Considerations

A biological product is defined as “a virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product, or analogous product, or arsphenamine, or derivative of arsphenamine or any other trivalent organic arsenic compound, applicable to the prevention, treatment or cure of a disease or condition of human beings”.^[1] Biological products, like other drugs, are used for the treatment, prevention or cure of disease in humans. Biologics were 7 of the top 10 bestselling drugs in recent years including 6 mAbs.^[2–4] They are usually produced by living cells and are generally large complex molecules, which are more difficult to characterize by nature, and can have significant heterogeneity. In addition to structural complexity, the source materials and manufacturing processes for protein and antibodies may lead to a variety of product variants and impurities that can impact product efficacy and safety. Manufacturing biologics is a complicated process. A biologic manufacturing process depends on many steps of production and purification processes which can influence the biological and clinical properties. These sophisticated steps are monitored by sensitive analytical methods, which need to be adapted to specific biological products. Therefore, it is the process that defines a biological product.

Regulatory

The regulatory science on which comparability is based has subsequently been applied to the review and approval of biosimilars.^[5] Similar Biologics Medicinal Products (“biosimilars”) have been on the market in the European Union since early 2006. In the United States, the FDA prefers to use the term “comparability” for changes made by a single manufacturer and “similarity” for applying this same process to biosimilars. By contrast, in Europe, the European Medicines Agency uses the term “comparability” when evaluating both inter- as well as intra-manufacturing changes. More recently, the European Medicines Agency has used the expression “biosimilar comparability” to clarify the context

Figure 1 Stepwise diagram for comparability studies

but not to change the concept as a scientific matter.^[6] However, these terms are used interchangeably here. A comparability study is formally defined as a quantitative assessment of the extent of similarity of drug substances and drug products made before and after a bioprocess change or between two products.^[7] The purpose of comparability studies is to ensure that the test product does not have any significant or clinically meaningful difference or changes that impact the material/product/process quality, safety, purity, and potency or efficacy compared to the reference product.^[7–12] The information submitted in the application for approval may include structural and functional characterization, nonclinical evaluation, human PK and PD data, clinical immunogenicity data, and clinical safety and efficacy data. This stepwise approach can be illustrated graphically as shown in [Figure 1](#), where (1) extensive characterization of the reference product using fingerprint-like techniques and (2) assessment of the variability among different reference batches, obtained from different regions and/or different manufacturing sites and manufactured over a broad window of time are completed to define the reference target product profile before the comparability study is performed.

Quality

Quality attributes (QA's) characterize a biological product in terms of its structural, physico-chemical and functional properties. Assessing analytical comparability involves the evaluation of data obtained from batch release testing, characterization testing, comparative stability studies and forced degradation studies. It is a key component in the overall comparison between a test product and a corresponding reference product. In view of the fact that manufacturers often test a large number of QA's, Tsong, Dong, et al.,^[13] recommend that the QA's be categorized into three tiers based on

their potential impact on product quality and clinical outcome. Whether or not the data generated on each QA are amenable to statistical analysis should also be considered when categorizing each assay. As shown in [Figure 2](#), the critical quality attributes (CQA's) are those assigned to Tier 1 and comparability should be statistically evaluated based on a comparison of means following an equivalence testing strategy. A “quality range” approach is recommended for the QA's assigned to Tier 2, and for QA's in Tier 3, a graphical comparison is sufficient. Evaluation of Tier 3 assay data will not be discussed in this entry.

Any strategy developed to characterize and compare the data must account for batch-to-batch variability since that is an important component of the overall variability in the data. This is especially true if batches are obtained

Figure 2 Investigational Strategies for Analytical Comparability Evaluation

from multiple regions (e.g., US and EU) or multiple manufacturing sites, are present in multiple images, or are of different ages. Selecting as many representative batches as possible and performing more assay runs for assays that have large variability (to define the reportable value) have direct impact on the relevance of the conclusions reached from the data analysis. This means that experience and judgment are necessary components to help guide the decision making process. However, because of manufacturing constraints, the number of available test product batches will usually be limited. When comparing a potential biosimilar to an innovator product, a manufacturer can purchase and test as many reference batches as necessary to generate an adequate sample size but it is not practical for the manufacturer to produce an equivalent number of test batches to achieve a balanced design. This is also true when a manufacturer is comparing batches produced after a manufacturing change to batches produced before the change. There may be a large number of existing pre-change batches that have data on the relevant attributes but likely only a few post-change batches will be available for testing. For comparative stability evaluation, the number of test or reference batches placed on stability will both be small, even under accelerated or stressed conditions.

Data Presentation

Some pharmacological data, such as potency or concentration, are generally right-skewed and have the characteristic that the standard deviation of the data increases proportionally to the mean. Standard statistical assumptions of normality and variance homogeneity are better satisfied if such data are first log transformed. Statistical calculations are performed on the transformed data and then converted back to the original scale. Conversion back to the original scale simply involves taking the anti-log of the metric calculated on the transformed data. Arithmetic means, standard deviations (SDs) and standard errors (SEs) become geometric means (GMs), geometric standard deviations (GSDs) and geometric standard errors (GSEs); “Mean $\pm$ SE” in the log scale becomes “GM $\times$ / GSE” in the original scale. It is recommended that the data are not rounded prior to statistical evaluation. The final results obtained from the statistical analysis should be rounded prior to presentation.

Before any formal comparison is performed, the collected data should be summarized using standard statistical approaches as described in Table 1. Unlike clinical endpoints, analytical data are heavily dependent on the assay, thereby limiting the interpretability of a 95% confidence interval (CI) as it relates to linking statistical difference or lack of difference to biological relevance. That is, a statistically significant difference does not necessarily imply the difference is biologically relevant. Nor does a conclusion of “not statistically significantly different” imply the compounds are biologically equivalent. Statistical findings must always be placed in the appropriate biological context.

Table 1 Recommended Data Summaries Prior to Formal Comparison

Data Source	Data Summary ^a
Reference	N ^b , Mean, SD ^c , 95% CI ^d , Box Plot
Test	N, Mean, SD, 95% CI, Box Plot
Reference + Test	95% CI for True Mean Difference

^aFor log-normal data perform analysis in log scale first and then convert back to the original scale; ^bSample size (number of batches); ^cStandard Deviation; ^dConfidence Interval

Tier 1 Evaluation: Statistical Equivalence Testing of Means

The measurements made on the reference product (X_R) are assumed to follow a normal distribution with mean μ_R and variance σ_R^2 , respectively. Likewise, the measurements made on the test product (X_T) are assumed to follow a normal distribution with mean μ_T and variance σ_T^2 , respectively. For a given equivalence margin, $\delta (> 0)$, the equivalence hypotheses can be stated as follows:

$$H_0 : |\mu_R - \mu_T| \geq \delta \text{ vs } H_1 : |\mu_R - \mu_T| < \delta \quad (1)$$

The most commonly used approach to testing H_0 is the two one-sided test (TOST) procedure.^[14–15] Recently equivalence testing has been expanded into much broader applications.^[16] Essentially TOST is a union-intersection test which decomposes the null hypothesis H_0 in Eq. 1 into two separate sub-null hypotheses $H_{01} : \mu_R - \mu_T \geq \delta$ and $H_{02} : \mu_R - \mu_T \leq -\delta$. Let ϕ_1 and ϕ_2 be the rejection regions, each at level α , for testing H_{01} and H_{02} , respectively. Then, by the union intersection principle, the rejection region for testing the hypothesis in Eq. 1 at level α is $\phi_1 \cup \phi_2$. More specifically, let $\bar{X}_R$, s_R^2 and n_R be the sample mean, sample variance and sample size for the reference product and let $\bar{X}_T$, s_T^2 and n_T be the sample mean, sample variance and sample size for the test product. Define

$$s_p^2 = \frac{(n_R - 1)s_R^2 + (n_T - 1)s_T^2}{n_R + n_T - 2} \text{ as the pooled sample variance.}$$

When it is feasible to assume that $\sigma_T^2 = \sigma_R^2$, the TOST procedure rejects the null hypothesis H_0 if

$$\frac{\bar{X}_R - \bar{X}_T + \delta}{s_p \sqrt{\frac{1}{n_R} + \frac{1}{n_T}}} \leq -t_\alpha \text{ or } \frac{\bar{X}_R - \bar{X}_T - \delta}{s_p \sqrt{\frac{1}{n_R} + \frac{1}{n_T}}} \geq t_\alpha \quad (2)$$

where t_α is the 100(1- α)th percentile of a T distribution with $n_R + n_T - 2$ degrees of freedom. When it is not feasible to assume $\sigma_T^2 = \sigma_R^2$, the test rejects H_0 in Eq. 1 if

$$\frac{\bar{X}_R - \bar{X}_T + \delta}{\sqrt{\frac{s_R^2}{n_R} + \frac{s_T^2}{n_T}}} \leq -t_\alpha^* \text{ or } \frac{\bar{X}_R - \bar{X}_T - \delta}{\sqrt{\frac{s_R^2}{n_R} + \frac{s_T^2}{n_T}}} \geq t_\alpha^* \quad (3)$$

where t_{α}^* is the $100(1-\alpha)\text{th}$ percentile of a T distribution with degrees of freedom approximated as

$$\left(\frac{s_R^2}{n_R} + \frac{s_T^2}{n_T} \right)^2 / \left(\frac{1}{n_R-1} \frac{s_R^2}{n_R} + \frac{1}{n_T-1} \frac{s_T^2}{n_T} \right) \quad (4)$$

Because of the close connection between hypothesis testing and confidence intervals, one expects that the TOST procedure is operationally identical to a procedure that compares some confidence interval for $\mu_R - \mu_T$ with the equivalence interval $(-\delta, \delta)$ and claims equivalence if this confidence interval is contained entirely within the equivalence interval. Westlake^[17] and Schuirmann^[18] noted one choice for such a confidence interval can be

$$(\bar{X}_R - \bar{X}_T) \pm t_{\alpha} \cdot s_p \sqrt{\frac{1}{n_R} + \frac{1}{n_T}} \text{ which has confidence level}$$

$(1-2\alpha)100\%$. Later Brown, Casella, et al.,^[19] called the relationship between the α level TOST and the above $(1-2\alpha)100\%$ confidence interval approach a coincidence. Berger and Hsu^[20] discussed examples where a $(1-2\alpha)100\%$ confidence interval approach is not a size α test, being either too liberal or too conservative, and also discussed cases where a $(1-\alpha)100\%$ confidence interval approach corresponds to an exact size α level TOST. These authors suggested that the practice of making a connection between a size α test and a $(1-2\alpha)100\%$ confidence interval be abandoned, and that $(1-\alpha)100\%$ confidence interval be reported instead when testing hypotheses of equivalence at a significance level of α . Although the above discussion has focused on symmetric equivalence intervals, equivalence testing can readily be extended to the asymmetric case whereby the equivalence interval is defined by $(-\delta_1, +\delta_2)$ for $\delta_1 > 0$, $\delta_2 > 0$ and $\delta_1 \neq \delta_2$. Only the symmetric case will be pursued in this entry.

Tier 1 Evaluation: Determination of the Equivalence Margin

The most crucial step in equivalence testing is the determination of the equivalence margin, δ , since the choice for it not only impacts the conclusion of the test but also the credibility of the study. Ideally δ would be prespecified and clinically meaningful or at least scientifically defensible. And while choosing a large value for δ increases the power to establish equivalence, it can also invite criticism from regulatory agencies unless such a choice is fully justified. In practice it is often quite challenging to provide a scientific basis for δ or link the choice to clinical efficacy endpoints or even Pharmacokinetic or pharmacodynamic (PK/PD) endpoints and consequently alternative approaches to determining δ need to be considered. As mentioned in the Introduction, it is common nowadays to choose $\log(1.25)$ for δ in bioequivalence studies in humans. In the context of a Tier 1 analytical evaluation, a one-size-fits-all approach is not practical since the impact

each CQA has on clinical efficacy or PK/PD endpoints, while unknown, is likely different. Also, the analytical methods used to evaluate the multiple CQA's possess different performance characteristics, such as different levels of precision. Before considering other approaches for determining δ , it should be emphasized that any statistically derived δ should be reviewed and agreed upon by appropriate subject matter experts before it is used in a statistical equivalence test.

The USP <1010>^[21] Approach

For comparing two analytical methods using statistical equivalence testing, Appendix E of USP <1010> describes an approach to the derivation of δ .^[21] This approach compares the specification limits for the quality attribute being measured with a [95/95] tolerance interval calculated based on the data generated by the reference method. In the context of comparing two procedures, the data from the reference or current procedure are used to generate the tolerance interval. In the context of assessing analytical comparability, the data from the reference product are used to derive the tolerance interval. Under the assumption of normality, a $[100(1-\alpha)/100p]$ tolerance interval (LTL , UTL) encloses $100p\%$ of the population of measurements with $100(1-\alpha)\%$ confidence.

Denote the lower and upper specification limits as LSL and USL respectively. The equivalence margin δ can be determined as the minimum of the two differences $LTL - LSL$ and $USL - UTL$, both of which need to be positive (see Figure 3). A mean shift of no more than δ implies a high probability that test product batches will be able to satisfy the same specification limits used to evaluate reference product batches. This method requires that specification limits be available and that the specification interval be wider than the 95/95 tolerance interval determined based on the reference data. When either of these conditions is not satisfied, the USP <1010>^[21] approach is not applicable. Because the width of a tolerance interval generally increases as the sample size decreases, this approach should only be used when there are a reasonable number of reference batches available for testing (say at least 20). This approach can easily be adapted to handle data from CQA's that only have a one-sided specification limit. In that case, a corresponding one-sided [95/95] tolerance bound would be constructed.

Figure 3 Illustration of the Derivation of $\delta = \min(A, B)$ using USP <1010> (Calculate $A = LTL - LSL$ for $LTL > LSL$ and calculate $B = USL - UTL$ for $USL > UTL$)

The Limentani, Ringo et al.,^[22] Approach

For a particular CQA, Limentani, Ringo et al.,^[22] proposed that the equivalence margin be chosen as $\delta = \delta_0 + s_R^* \left[t_{1-\alpha, 2n-2} + t_{1-\beta, 2n-2} \right] \frac{2}{\sqrt{n}}$, where δ_0 is an acceptable shift as determined by appropriate subject matter experts (if δ_0 is unknown it can be conservatively set to zero); n is the common sample size (number of batches) for both test and reference products that is fixed before the determination of δ ; $s_R^* = s_R \sqrt{\frac{n-1}{\chi_{\gamma, n-1}^2}}$ is the upper $100(1-\gamma)\%$

confidence bound for the true standard deviation σ_R associated with the reference product, $t_{1-\alpha, 2n-2}$ ($t_{1-\beta, 2n-2}$) is the upper $100(1-\alpha)\text{th}$ ($100(1-\beta)\text{th}$) percentile of the Student's T distribution with $2n-2$ degrees of freedom and $\chi_{\gamma, n-1}^2$ is the upper $100(1-\gamma)\text{th}$ percentile of the Chi-Squared distribution with $n-1$ degrees of freedom. Here α and β are the allowed Type I and Type II errors of the TOST procedure and therefore this recommended δ is closely related to the power of the test. If a point estimate, s_R , of σ_R is used in the definition of the δ instead of the upper confidence bound, s_R^* , then the corresponding TOST will have power equal to $1-\beta$, when the sample sizes for reference and test products are indeed equal. As δ is a function of the sample size n , it can be large when n is small.

The Tsong, Dong, et al.,^[13] Approach

The statistical determination of δ should follow a unified approach for all Tier 1 CQA's and allow for possibly different variabilities among the corresponding analytical methods. Tsong, Dong et al.,^[13] propose to use a sample size and variance adjusted margin that rewards large sample sizes but controls the power of the TOST procedure for small sample sizes. Similar to Limentani, Ringo et al.,^[22] they consider that δ be represented as $\delta_0 + k\sigma_R$, where $\delta_0 \geq 0$ is an acceptable shift as determined by subject matter experts ($\delta_0 = 0$ by default); $k > 0$ is some positive number and σ_R is the true standard deviation associated with the reference product. Let n be the common sample size (number of batches) for both reference and test products and assume $\sigma_T^2 = \sigma_R^2 = \sigma^2$, where σ_T represents the true standard deviation associated with the test product. If the true mean difference (i.e., true effect) to be detected is also defined as a multiple η of σ_R ($\eta > 0$) then for $\delta_0 = 0$ the power of the TOST procedure defined in Eq. 2 can be expressed as a function of n , α , k and η :

$$\begin{aligned} \text{Power} &= \beta(n, \alpha, \eta, k) \\ &= E_X \left[\Phi \left(\frac{k-\eta}{\sqrt{2/n}} - t_{\alpha, 2(n-1)} \sqrt{\frac{X}{2(n-1)}} \right) \right. \\ &\quad \left. - \Phi \left(\frac{-k-\eta}{\sqrt{2/n}} + t_{\alpha, 2(n-1)} \sqrt{\frac{X}{2(n-1)}} \right) \right] \end{aligned} \quad (5)$$

where the expectation is taken with respect to X which follows a Chi-squared distribution with $2(n-1)$ degrees of freedom. Having chosen a fixed $\eta = 1/8$, as well as fixed values for n and α , they consider determining k , or equivalently δ , by assigning, for each value of n , a value for power based on the function $f(n) = 1 - \exp(-0.53948 - 0.14694n + 0.00205n^2)$. The function $f(n)$ is determined based on the rationale that larger power should correspond to larger sample sizes but still be reasonable for small sample sizes. Specifically, based on discussions between FDA statisticians with FDA biologists, initial power values were assigned to five different sample sizes, ranging from 65% power for $n = 4$ to 95% power for $n = 25$.^[13] To generate a generally applicable power function, a monotonic exponential function was fit through the five values to obtain the function $f(n)$ described above. To illustrate the methodology, given $\eta = 1/8$ and $\alpha = 0.05$, for specific n , say $n = 10$, a value for k can be found so that the above expectation in Eq. 5 is equal to $f(10) = 0.84$. The process of finding k in this example can be illustrated using Figure 4 below.

Alternatively, one can fix k and report the corresponding value for α . This is their final proposed approach. Specifically, given $\eta = 1/8$ and $k = 1.5$, for a specific n , a value for α can be found so that the above expectation in Eq. 5 is equal to $f(n)$. This process is illustrated in Figure 5 below using the same inputs as above.

In situations where one or more of the three conditions, $\delta_0 = 0$, $\sigma_T^2 = \sigma_R^2 = \sigma^2$ or $n_T = n_R = n$, cannot be assumed, the power function $\beta(n, \alpha, \eta, k)$ in Eq. 5 can be adjusted

Figure 4 Illustration of the determination of k for fixed n , α , and η based on Tsong, Dong, et al.,^[13]. The blue solid curve is the graph of $\beta(n, \alpha, \eta, k)$ as a function of k , with $n = 10$, $\alpha = 0.05$ and $\eta = 1/8$. The horizontal red dotted line represents the power assigned to $n = 10$, namely $f(10)$, which equals 0.84 in this example. The vertical red dotted line represents the value of k where $\beta(n, \alpha, \eta, k) = f(10)$. In this example, $k = 1.4$

Figure 5 Illustration of the determination of α for fixed n, k , and η based on Tsong, Dong, et al.,^[13]. The blue solid curve is the graph of $\beta(n, \alpha, \eta, k)$ as a function of α , with $n = 10, k = 1.5$, and $\eta = 1/8$. The horizontal red dotted line represents the power assigned to $n = 10$, namely $f(10)$, which equals 0.84 in this case. The vertical red dotted line represents the value of α where $\beta(n, \alpha, \eta, k) = f(10)$. In this example, α equal 0.04

accordingly and the calculations described above would be based on the adjusted power function instead.

The Liao and Darken^[23] Approach

Chow^[24] pointed out some concerns regarding the approach recommended by Tsong, Dong et al.,^[13]. One main concern is that the model structure assumed that one observation was obtained per batch for both reference and test products. In fact, this assumption was also made in Limentani, Ringo, et al.,^[22] and by the USP <1010>^[21] approach for the determination of δ . Under this assumption, batch-to-batch variability is not estimable separately from analytical variability. In reality there is often heterogeneity among the batches and it is therefore important to separate between-batch variability from within-batch (or analytical) variability when estimating σ_R . Otherwise, σ_R will likely be underestimated resulting in overly narrow equivalence interval. Another concern is with regard to the recommended choice of $k = 1.5$ in their proposed approach, since no scientific justification for this particular selection was provided.

Liao and Darken^[23] and Liao^[25] considered the data structure where multiple observations are taken from multiple batches for both reference and test products. Specifically, let X_{ij} be the j th observation taken from the i th reference batch, $i = 1, \dots, m_X; j = 1, \dots, n_X$, with m_X being the number of reference batches and n_X being the number of observations obtained on each reference batch. Similarly, let Y_{ks} be the s th observation taken from the k th test product batch, $k = 1, \dots, m_Y; s = 1, \dots, n_Y$, with m_Y being the number

of test product batches and n_Y being the number of observations obtained on each test product batch. They considered the following random effect model for X_{ij} and Y_{ks} :

$$X_{ij} = \mu_X + \tau_X + \varepsilon_{ij} \text{ and } Y_{ks} = \mu_Y + \tau_Y + \delta_{ks} \quad (6)$$

where μ_X (μ_Y) is the overall mean for reference (test) product; $\tau_X \sim N(0, \sigma_{\tau_X}^2)$ and $\tau_Y \sim N(0, \sigma_{\tau_Y}^2)$ are random batch effects for reference and test product, respectively, with $\sigma_{\tau_X}^2$ and $\sigma_{\tau_Y}^2$ being the corresponding process or batch-to-batch variability; ε_{ij} is the random error term for the reference product, assumed to be identically and independently distributed as $N(0, \sigma_\varepsilon^2)$ and δ_{ks} is the random error term for the test product assumed to be identically and independently distributed as $N(0, \sigma_\delta^2)$. Here σ_ε^2 and σ_δ^2 represent the corresponding within-batch or assay variabilities.

It is assumed that (1) the ε_{ij} 's and δ_{ks} 's are independently distributed and (2) τ_X and τ_Y are independent of each other. Note that in this set-up the variability of any reference (or test) measurement contains two components: one representing batch-to-batch variability and the other within-batch or assay variability. The proposed acceptance criterion for assessing equivalence is derived based on the reasoning that any difference observed when comparing reference product to itself is a result of only random variation and not some underlying non-random cause. Such random variation can be quantified by a *plausibility interval* for the differences obtained from reference-to-reference comparison. Specifically, for $k > 0$, the plausibility interval is defined as

$$\left(-k \sqrt{2(\hat{\sigma}_{\tau_X}^2 + \hat{\sigma}_\varepsilon^2)}, +k \sqrt{2(\hat{\sigma}_{\tau_X}^2 + \hat{\sigma}_\varepsilon^2)} \right) \quad (7)$$

where $\hat{\sigma}_{\tau_X}^2$ is an estimate of the reference batch-to-batch variability and $\hat{\sigma}_\varepsilon^2$ is an estimate of the reference assay variability. Equivalency is claimed if (1) the calculated $[100(1 - \alpha)/100p]$ tolerance interval for the differences between the reference and test products fall within the pre-determined plausibility interval and (2) the estimated mean ratio of reference to test must be within some pre-specified range, for example (0.8, 1.25), as might be used in an average bioequivalence study. Based on a simulation study, the authors suggest that k in Eq. 7 can be chosen to be 3. Their simulation studies revealed that the requirement on the mean ratio is necessary since it adds protection against making a Type I error and that it is important to account for batch-to-batch variability as it plays a significant role in the power of the test. The assessment procedure developed here is suitable for both paired and non-paired data structures. However, the mathematical formula to calculate the plausibility interval is different depending on whether the data are paired or non-paired. The ability to design a comparability study to exploit a paired-data structure is advantageous since it reduces the total variability in the data by removing batch to batch variability resulting in a greater

probability of claiming equivalence when there is truly no difference between the test and reference products.

Tier 2 Evaluation: Quality Range

Analytical results for each test designated for Tier 2 analysis are evaluated using criteria based on constructing intervals defined by the assay results from the batches of reference product. Since methods for constructing such intervals often rely on the assumption of normality, the data should be plotted to confirm that this assumption is not seriously violated. For some attributes, the data may need to be transformed to better approximate a normal distribution. When severe departures from normality occur and none of the common transformations help alleviate the problem, alternative statistical methods (e.g., distribution-free methods) can be considered. A statistician should be consulted for advice.

Assume the measurements made on the reference product (X_R) follow a normal distribution with mean μ_R and variance σ_R^2 , respectively. Here σ_R represents the total standard deviation (batch-to-batch and within-batch) of the population. Following Tsong, Dong et al.,^[13] a probability interval or *quality range* for the reference is an interval of the form $\mu_R \pm f\sigma_R$ for some value f . If μ_R and σ_R are known, then about 95% of the population of measurements made on the reference batches will fall between $\mu_R \pm 2\sigma_R$ (95% coverage) and about 99.7% of the population of measurements will fall between $\mu_R \pm 3\sigma_R$ (99.7% coverage). There are a number of approaches used to estimate a quality range and the most common approaches are shown in Table 2. The choice opted for should be discussed with regulatory agencies prior to implementing it.

The Tolerance Interval Approach

As described previously, under the assumption of normality, a $[100(1-\alpha)/100p]$ tolerance interval (*LTL*, *UTL*) encloses $100p\%$ of the population of measurements with $100(1-\alpha)\%$ confidence. It is calculated as $\hat{\mu}_R \pm g_{(1-\alpha;p,n)}\hat{\sigma}_R$ where $g_{(1-\alpha;p,n)}$ is the tolerance factor and depends on the

coverage probability, confidence level and sample size, n , the number of reference batches. In most practical applications, $1-\alpha$ and p are typically chosen from the set of values {0.90, 0.95, 0.99}. Tables exist that provide exact values for $g_{(1-\alpha;p,n)}$ for various choices of p , α and n when the data arise from a simple random sample.^[26] For more complicated data structures, for example, nested data, a statistician should be consulted. In practice, assuming comparability, it is expected that the entire available test product batch data (reportable values) would fall within the tolerance interval constructed from the reference product batch data for each attribute. It is possible, though, that one batch might fall outside of the tolerance interval for a particular attribute. The implication of such a sporadic result would need to be discussed among the appropriate subject matter experts and any conclusion of comparability (or lack thereof) would be based on the totality of the evidence, not just this one result for one particular attribute. If two or more of the test product batches fall outside of the tolerance interval for a particular attribute, then this should be thoroughly investigated before an overall conclusion of comparability is made as this outcome would not be expected under the assumption of comparability. If the calculated tolerance interval is wider than the current release specification interval, then the specification interval should be used to gauge analytical comparability. A tolerance interval can be very wide when n is relatively small. Generally this approach is suitable when n is at least 20 or 25 reference batches.

The Prediction Interval Approach

Suppose a random sample of n reference product batches are independently obtained and assume the resulting measurements follow a normal distribution with mean μ_R and variance σ_R^2 , respectively. Let $\hat{\mu}_R$ and $\hat{\sigma}_R$ be the corresponding estimates obtained from the sample measurements. Following Hahn and Meeker,^[26] a two-sided $100(1-\alpha)\%$ prediction interval to contain the values obtained on all of m randomly selected test product batches is $\hat{\mu}_R \pm r_{(1-\alpha;m,n)}\hat{\sigma}_R$ assuming the observations obtained on the test product

Table 2 Common Approaches for Estimating a Quality Range

Approach	Description	Comment
Tolerance Interval	Cover a large proportion of the population with a stated confidence	Very wide with small samples sizes (number of reference batches); suitable when number of reference batches at least 20 or 25 batches.
Prediction Interval	High confidence that all of a pre-specified number of future batches included in the interval	Useful when the number of test batches is known <i>a priori</i> ; can be wide when the number of reference batches is small.
Process Capability Interval	Sample equivalent of the quality range ($\hat{\mu}_R \pm f\hat{\sigma}_R$)	Often used in setting acceptance criteria and is easy to understand; recommended by Tsong, Dong et al., ^[13]
Data Range	Minimum of data to Maximum of data	Coverage can be poor for small sample sizes; simple to use but not recommended

batches follow the same normal distribution as the measurements obtained on the reference product batches. Exact values for $r_{(1-\alpha;m,n)}$ are available.^[26] If one or more of the test product batches generate data falling outside of the prediction interval then it is likely that the data obtained on the test batches do not arise from the same population that generated the data obtained on the reference batches. This approach is useful when m is known in advance. Similar to a tolerance interval, a prediction interval can be wide when n is small, especially for large m .

The Process Capability Interval Approach

This approach simply replaces the population mean and variance in $\mu_R \pm f\sigma_R$ with their sample estimates, $\hat{\mu}_R$ and $\hat{\sigma}_R$. When the number of reference batches is large (> 50) this approach is viable. As n decreases, the increasingly poor coverage offered by the process capability interval is not compensated for by the simplicity of the calculations. For example, based on the observations obtained on $n = 14$ reference batches, suppose a naïve user constructs the interval $\hat{\mu}_R \pm 3\hat{\sigma}_R$. The user may believe that about 99.7% of the population of measurements will be enclosed by this interval. But, in fact, he or she would be mistaken since for $n = 14$ the tolerance factor associated with a [95/95] tolerance interval is 3.024 and therefore only approximately 95% of the population will be enclosed by the interval with 95% confidence.

The Data Range Approach

Reporting the minimum and maximum of the data is sensible but unless n is extremely large (in the order of hundreds), defining the quality range as the interval spanning the minimum observation to the maximum observation should be avoided since it will have poor coverage.

Tier 2 Evaluation: Variability Comparison

Besides generating a quality range that is expected to enclose the measurements obtained on the test product batches, it might also be important to construct a prediction bound to exceed the standard deviation of the test batch data based on the data obtained on the reference batches. Suppose independent observations are obtained on n randomly sampled reference batches. Further, suppose the data follow a normal distribution with mean μ_R and variance σ_R^2 , respectively. Let $\hat{\sigma}_R$ be the (reference) sample standard deviation. Following Hahn and Meeker,^[26] a one-sided $100(1 - \alpha)\%$ upper prediction bound to exceed the standard deviation ($\hat{\sigma}_T$) of the observations obtained on m test product batches is $\hat{\sigma}_R \sqrt{F_{(1-\alpha;m-1,n-1)}}$, assuming the observations obtained on the test product batches follow the same normal distribution as the measurements obtained on the reference product batches. $F_{(1-\alpha;m-1,n-1)}$ represents the

upper $100(1 - \alpha)\%$ th percentile point from an F distribution with numerator degrees of freedom equal to $m - 1$ and denominator degrees of freedom equal to $n - 1$. Exact values for $F_{(1-\alpha;m-1,n-1)}$ for various choices of α , m and n are available.^[26] If the standard deviation of the test batch data exceeds the prediction bound derived from the reference batch data then it is likely that the test data do not arise from the same population that generated the reference data. Since the same analytical method is used to assay both reference and test batches, the likelihood of such an occurrence is low unless there is a significant differences in the among-batch variability for the test product batches compared to the reference product batches. Completing the variability assessment is therefore important since such an outcome could impact how the quality range is derived.

Comparative Stability Evaluation: Statistical Equivalence Testing of Slopes

Stability is an important quality attribute for many products. When comparing a reference product to a test product, comparative stability testing is required to confirm that changes over time in each of the pertinent QAs are equivalent. In this section methods developed for evaluating trends (i.e., slopes) are discussed as part of the overall assessment of similarity or comparability. Assessing equivalence of the intercepts is not considered since that is essentially the same as testing the equivalence of means as discussed previously as part of a Tier 1 analysis.

The four approaches described in Table 3 are the most common strategies employed to compare slopes. Schofield^[27] evaluates each of them in terms of vaccine potency but his conclusions apply to any stability indicating attribute. He recommended that an equivalence testing approach be utilized for evaluating the slopes obtained from comparative stability testing. For attributes that are not considered crucial, a quality range type of approach is a reasonable alternative. With any equivalence testing approach, the choice of equivalence margin is critical.

Comparative Stability Evaluation: Choice of Equivalence Margin for Comparing Slopes

The Schofield^[27] Approach

For determining the equivalence margin, δ , assume that the reference product changes according to some known rate β and let T_E be the exposure time, which is the time from release to expiry. Denote the measurement of reference product at release as X and the measurement of reference product at expiry as Y . Assume that the distribution of the release data X and distribution of the degradation rate β can both be determined based on historical data and experience. Then simulate data x^* and β^* based on the release distribution and degradation rate distribution respectively

Table 3 Four Approaches for Comparing Slopes

Approach	Description	Comment
Comparison to Specification	Test product data are compared against established stability specification limits; comparability established if all data fall within the limits	Highly risky even when reference and test product are comparable since the probability that all measurements obtained on the test product batches are contained within the specification limits can be extremely small, especially when assay variability is large. Conversely, when the reference and test products are not comparable, the criteria could nevertheless be satisfied.
Quality Range	Requires that slopes derived from analysis of data generated on the test product batches fall within a range of slopes established from the analysis of the data obtained on the reference product batches	The limits of the quality range may not align with slope differences considered to be scientifically important. For example, even though all the data generated on the test product batches fall inside the quality range determined based on the data generated on reference product batches, the two sets of data can still have very different stability trends. On the other hand, the fact that some data corresponding to the test product fall outside of the quality range based on the reference product does not necessarily mean a difference between the stability trends in the two sets of the data.
Hypothesis Testing	Requires a decision to “not reject” the null hypothesis of parallelism: H_0 : Slope Difference = 0 vs H_1 : Slope Difference $\neq$ 0	The conclusion to reject or not reject H_0 depends highly on the variability in the data. Very precise data exhibiting little difference in slopes can nevertheless lead to the rejection of H_0 . Conversely, highly variable data can lead to the conclusion to not reject H_0 even if there visually appears to be a large difference in the slopes. Lastly, the null hypothesis of equal slope (parallelism) may not be of interest in practice
Equivalence Testing	Requires a decision to “reject the null hypothesis of non-equivalence” to demonstrate the slope difference is within an acceptance range. H_0 : Slope Difference > δ vs H_1 : Slope Difference $\leq$ δ	The choice of δ is critical and should relate to slope differences that have scientific or clinical relevance

to determine a measurement at expiry as $y^* = x^* - \beta^* T_E^*$ where T_E^* should be determined based on some criterion, for example, the expiry specification of the product. This process can be repeated many times to obtain sufficient measurements at expiry based on which the distribution of Y can be estimated. This distribution can then be used to establish a shift in reference measurements at expiry, ΔY , and the equivalence margin δ can then be determined as $\delta = \Delta Y / T_{SL}$, where T_{SL} is the shelf-life of the reference product.

This approach is not appropriate for attributes that do not change much or at all over time under normal storage conditions ($\beta \approx 0$). For such attributes, accelerated comparative stability studies are required since then β is likely not near 0. Also, in practice, it may be difficult to decide upon a proper value for β , especially at accelerated conditions since usually there is little experience with the stability of the reference product under these conditions. Preliminary studies can be performed to provide this information.

The Burdick and Sidor^[28] Approach

Assume the stability profiles are consistent from batch-to-batch and denote the measurements taken from i^{th} lot and j^{th} time point as X_{ij}^R and X_{ij}^T respectively for the reference

product and test product. Then following Burdick and Sidor,^[28] the stability data can be modeled as:

$$\begin{aligned} X_{ij}^R &= \mu^R + \tau_i^R + \beta^R t_j + \varepsilon_{ij}^R, \quad i = 1, \dots, n_R; j = 1, \dots, T_R \\ X_{ij}^T &= \mu^T + \tau_i^T + \beta^T t_j + \varepsilon_{ij}^T, \quad i = 1, \dots, n_T; j = 1, \dots, T_T \end{aligned} \quad (8)$$

where

1. μ^R and μ^T are the means at the initial time point for the reference and test products;
2. τ_i^R and τ_i^T are the random intercept terms for the reference and test products for the i^{th} batch, both of which assumed to be distributed as $N(0, \sigma_\alpha^2)$;
3. β^R and β^T are the true slopes for the reference and test products;
4. t_i is the i^{th} time point;
5. ε_{ij}^R and ε_{ij}^T are the residual error terms for the reference and test products, both of which assumed to be distributed as $N(0, \sigma_\varepsilon^2)$; Here ε_{ij}^R , ε_{ij}^T , τ_i^R and τ_i^T are assumed to all be independent.
6. n_R and n_T are the total number of batches included for the reference and test products;
7. T_R and T_T are the total number of time points for the reference and test products and generally taken to be the same value, T .

While the authors were interested in deriving the equivalence margin, δ , in an accelerated stability study under non-recommended conditions in the context of evaluating a process change, their approach can be utilized to compare slopes between a reference product and test product in the context of an analytical comparability evaluation. Their approach can also be used for product stored under recommended conditions although in this case the resulting δ must be gauged against existing product specifications. The risk that a test product batch fails its specification might be deemed acceptably small even if the difference in slopes is outside of the equivalence interval for one or more attributes. The strategy discussed in Schofield^[27] can also be used for deriving δ .

Under the model given in Eq. 8, the null and alternative hypotheses to be tested for demonstrating slope equivalence are $H_0: |\beta^R - \beta^T| \geq \delta$ vs. $H_1: |\beta^R - \beta^T| < \delta$. The TOST procedure previously discussed can then be modified to perform this test. That is, H_0 is rejected if the two-sided confidence interval for $\beta^R - \beta^T$ is contained within the equivalence interval $(-\delta, \delta)$. Since it is difficult to ascertain what difference in slopes might be considered acceptable, especially under accelerated conditions, Burdick and Sidor^[28] propose that the equivalence margin be determined based on *effect size*, which expresses the absolute difference in the true slopes in terms of the variability associated with the least squares estimator of β^R . That is, effect size (ES) is defined as $ES = |\beta^R - \beta^T|/\sigma_R$, where in this case σ_R is the standard deviation corresponding to the least squares estimate of the slope obtained from the data generated on the reference product batches. Upon rearranging the equation for ES, the authors define the equivalence margin as $\delta = ES \times \sigma_R$. Under the assumptions stated above for the

model given in Eq. 8, $\sigma_R = \sqrt{\frac{\sigma_e^2}{\sum_i (t_i - \bar{t})^2}}$ with $\bar{t} = \frac{1}{T} \sum_i t_i$.

Through a simulation study the authors show that an ES of 2 is a reasonable choice. However, the choice should be justified for each specific situation; subject matter expert input is required. The residual error variance term, σ_e^2 , can be determined from an analytical method qualification or validation study, or from a prior stability study performed on the reference product. In some cases the use of an upper confidence bound (instead of the point estimate) can be considered to account for the uncertainty in the estimate.

Alternative model formulations may be necessary to better describe the data. For example, including both random intercept and random slope terms in the model is feasible when variation beyond the residual variability could impact the slope estimates. Also, using a fixed intercept model makes sense when the data at the initial time point exhibit very little variation. For example, the level of impurity at time 0 may be nearly 0% (below the limit of quantitation) for all batches in the study. Sometimes a simpler model must be utilized to achieve convergence in the numerical algorithm used to estimate

the model parameters. Whatever the reason is for using an alternative model, the derivation of the ES and the corresponding equivalence margin must be modified accordingly.

EVALUATING THE CLINICAL COMPARABILITY OF A BIOLOGICAL PRODUCT

Pharmacokinetic (PK) comparability

Typically, an equivalence approach is used to demonstrate the comparability of pharmacokinetic (PK) measurements of the test product and the reference product. To demonstrate equivalence, the 90% confidence interval (CI) for the true geometric mean ratio (GMR) of the test product relative to the reference product for both area under the curve (AUC) and maximum serum concentration (Cmax) must fall between the predefined limits of 0.80 and 1.25.^[29,30] However, due to the usually high variability for biological products resulting from the complexity and the possible pleiotropic activities of biologics, the CI of the estimated GMR could be too wide with commonly acceptable sample size. Consequently, there is a high probability of the constructed CI falling out of the predetermined limits (0.8, 1.25), which can lead to an unacceptably high producer risk. Many different approaches have been proposed for high variability drug products to manage the producer risk under a reasonable sample size requirement. The type of acceptance criteria using the reference-scaled method proposed by the FDA working group rather than the traditional equivalence criteria is recommended for the demonstration of PK comparability in this situation. The acceptance criteria are scaled based on the variability of the reference product resulting in a reduction of the producer risk without increasing the consumer risk.

Let μ_T and μ_R be the true means of a logarithmic pharmacokinetic response (e.g., AUC or Cmax) corresponding to the test and the reference products, respectively. The classical paradigm for the determination of equivalence of a test product to the reference product is to require the 90% confidence interval for the difference of means between the test and the reference fall within the predetermined equivalence interval ($\log(0.8)$, $\log(1.25)$). This is equivalent to evaluating Eq. 1 with $\delta = \log(1.25) \approx 0.233$ (using log base e). This approach does not depend on the underlying variability, or the ratio of geometric means of the PK parameters. To reduce the producer risk when product variability is high, without resorting to unrealistically large sample sizes, Haidar, Davit et al.,^[31] and Haider, Makhoul, et al.,^[32] compared several approaches and proposed the following reference-scaled criterion

$$(\mu_T - \mu_R)^2 / \sigma_{WR}^2 - \theta_F \leq 0 \quad (9)$$

where $\theta_F = \frac{(\log(1.25))^2}{\sigma_{w0}^2} = \frac{(\log(1.25))^2}{0.25^2} \approx 0.8$ using a “switching” variability σ_{w0} as a tool to control the sponsor risk, and σ_{wR}^2 is the within-subject variance for the reference product for a cross-over design but represents the total variance for the reference product for a parallel design. Comparability is claimed if the upper 95% CI for the parameter on the left side of Eq. 9 is negative or zero, and the point estimate of the GMR (test/reference estimated geometric mean ratio) falls within (0.8, 1.25). This approach is currently recommended by the FDA. Comparing to the traditional equivalence approach, the reference-scaled approach could effectively decrease the sample size needed for the demonstration of comparability.^[32] The additional point-estimate constraint eliminates the potential that a test product with a large mean difference would enter the market due to large variability in the reference product.

In terms of risks in evaluating PK comparability, it is clear that a larger switching variability is needed to control the consumer risk, while a smaller switching variability is needed to control the producer risk. However, the FDA recommended approach uses a single fixed switching variability. When there is no mean difference between the reference and the test products, the ideal test will have a high probability of accepting comparability. If the reference product is compared to the reference itself (i.e., True GMR = 1), then it should always be comparable regardless of the variability. However, for this case, the FDA ACPS method only gives 74% chance of accepting comparability, and leads to a large producer risk. In other words, the switching variability is too large in this case and a smaller switching variability should be used. In the other direction, a switching variability that is too small will lead to a large consumer's risk. For a more reasonable balance and control of the two risks, Liao and Heyse^[33] proposed using two switching variabilities: one for controlling the producer risk when the true GMR = 1, where a high probability of concluding comparability is desired, and a second one for controlling the consumer risk when the true GMR = 1.25, where a low probability of concluding comparability is desired. For this purpose, the authors proposed a new reference-scaled approach using the criterion

$$(\mu_T - \mu_R)^2 / \sigma_{wR}^2 - 2\theta_L(GMR) \leq 0 \quad (10)$$

Where $\theta_L(GMR) = [\log(1.25) / (\sqrt{2} \times (3.763 \times GMR - 2.763) \times 0.152)]^2$, and σ_{wR}^2 is the within-subject variance for the reference product for a cross-over design but represents the total variance for the reference product for a parallel design. Here, the switching variability is a function of the GMR. The GMR should always be greater than or equal to 1. If it is believed that the true PK parameter corresponding to the test product is less than that of the reference product replace GMR with 1/GMR in Eq. 10. Comparability is claimed if the upper 95% CI for the parameter on the left side of Eq. 10 is negative or zero.

For the criteria described Eq. 9 or Eq. 10, an approximate linearized regulatory model of the form $\eta = X^2 - cY^2 \leq 0$ is suggested^[34] where $\eta = (\mu_T - \mu_R)^2 - \theta_F \sigma_{wR}^2 \leq 0$ for Eq. 9 and $\eta = (\mu_T - \mu_R)^2 - 2\theta_L(GMR) \sigma_{wR}^2 \leq 0$ for Eq. 10, which would require a more complicated calculation to construct the confidence interval. The sampling distribution of the approximate linearized regulatory model is complicated but can be approximated by a non-central t-distribution or even a normal distribution when the number of subjects is large.^[35] Thus, a non-central t-distribution or a normal approximation could be used to calculate the confidence limits rather than the more complicated linearized regulatory model as all three have similar operating characteristics.

The performance of the two reference scaled approaches was compared using a simulation study and by way of an example. As detailed in Liao and Heyse,^[33] when there is no subject-by-product interaction and no mean shift (true GMR = 1), the criterion given by Eq. 10 leads to an 85% probability of concluding comparability compared to 74% for the FDA approach (Eq. 9) thereby lowering the producer risk. In this case, the switching variability, σ_{w0} , is 0.152. When there is a mean shift, i.e., when the true GMR = 1.25, the switching variability $\sigma_{w0} = 0.292$ is used for controlling the consumer risk. Third, the approach in Eq. 10 gives a narrower boundary for a larger GMR, which is very reasonable since the probability of claiming comparability should be getting smaller when GMR is deviating from 1. In fact, optimal switching variabilities can be derived based on pre-specified consumer and producer risks, chosen to be acceptable to both the manufacturer and the regulatory agency. For two given switching variabilities, σ_{w1} and σ_{w2} , the values for $\theta_L(GMR)$ in Eq. 10 would be $\theta_L(GMR) = [\log(1.25) / (\sqrt{2} \times ((a+1) \times GMR - a) \times \sigma_{w1})]^2$, where $a = 4 \times \sigma_{w2} / \sigma_{w1} - 5$, σ_{w1} is the smaller switching variability controlling the producer risk and σ_{w2} is the larger switching variability controlling the consumer risk.

Pharmacodynamic (PD) profile comparability

It is challenging to assess pharmacodynamic (PD) profile comparability. Varki, Pequignot et al.,^[36] and Waller, Bronchud et al.,^[37] used the classical equivalence rule for PD comparison in terms of the area under the effect curve (AUEC) of the PD profile. Recently, the FDA issued a guidance document for conducting a PD comparability study using this rule.^[30] However, this may not be a meaningful approach since the interpretation for AUEC used in PD studies is not the same as for PK studies since PK describes what the body does to the drug while PD describes what the drug does to the body. Since the AUEC is summarized before the PD profile is compared directly, the same AUEC value does not necessarily imply the same PD profile. The objective of evaluating PD comparability is to directly compare the entire PD profile. A single AUEC assessment of the PD profile may not be sensitive enough.

To directly compare two PD profiles, Liao and Darken^[38] proposed a PD comparability index, f_{PD} , using the entire profile as shown in Eq. 11.

$$f_{PD} = \frac{\min(R_{\max}^R - R_{\min}^R, R_{\max}^T - R_{\min}^T)}{\max(R_{\max}^R - R_{\min}^R, R_{\max}^T - R_{\min}^T) + \sqrt{\frac{1}{n} \sum_{j=1}^n w_j (y_j^R - y_j^T)^2}} \quad (11)$$

where n is the total number of time points in the PD profile; y_j^R and y_j^T are the predicted PD responses at time t_j for the reference and the test product, respectively; w_j is the optional weight for controlling the contribution at time t_j to the overall evaluation, and $R_{\max}^R$ ($R_{\min}^R$) and $R_{\max}^T$ ($R_{\min}^T$) are the predicted maximum (minimum) profile response for the reference and the test product, respectively. The PD comparability index falls within $[0, 1]$ with larger values of f_{PD} implying closer agreement between the two PD profiles. An f_{PD} of 1 indicates 100% comparability, i.e., the two profiles are identical. PD comparability is claimed if (1) The approximate lower 95% confidence limit of the PD comparability index f_{PD} for the test against the reference is greater than a value δ_0 and (2) The point estimate of

δ_0 as the maximum of the two values. The second requirement in the acceptance criteria ensures that no major difference in the PD profiles passes the comparability assessment due to large variability in the reference product, which is not unusual for a biological product.^[31–32] Selecting a value of $\delta_1 = 0.9$, which is about 10% difference in the means, could be a reasonable value for use.

To estimate the value of f_{PD} in Eq. 11, the corresponding parameters can be obtained by fitting a model such as the Emax model or the extended Emax model^[39] or by using a non-parametric method to determine a smooth curve (spline) of the PD profile. To construct the lower 95% confidence limit for f_{PD} when comparing the reference profile to itself, a bootstrap method is recommended. The residuals are bootstrapped a large number of times (N) and the PD model is re-fitted N times using the bootstrapped data. The lower 5th percentile of the bootstrapped determinations of the PD comparability index is then used as the approximate 95% lower confidence limit. For comparing the test product profile to the reference product profile using non-parametric spline fits, the lower confidence band can be constructed using the method in Hastie and Tibshirani,^[40] as provided in Eq. 12.

$$\frac{\min(R_{\max}^R - R_{\min}^R, R_{\max}^T - R_{\min}^T)}{\max(R_{\max}^R - R_{\min}^R, R_{\max}^T - R_{\min}^T) + \sqrt{\max \left\{ \frac{1}{n} \sum_{j=1}^n w_j (y_j^R - y_j^T \pm z_{0.975} \sqrt{S_R^2 + S_T^2})^2 \right\}}} \quad (12)$$

f_{PD} is greater than a value δ_1 . The two boundaries δ_0 and δ_1 should be pre-specified and agreed to by regulatory authorities.

The boundary δ_0 in the acceptance criteria takes into account variability in the reference product. One way to choose δ_0 is to use the reference comparison as the basis for making a comparison between the test and the reference product. When the reference and the test PD profiles are very close, the two confidence interval limits, one from the reference against itself and the other from the test against the reference, are also close to each other, as expected. Considering this outcome, first calculate the approximate lower 95% confidence limit of the PD comparability index based on evaluating the reference against itself. Then, choose δ_0 equal to a fraction, c ($0 < c < 1$), of this approximate lower limit as the threshold for comparing the test profile against the reference profile. One suggestion is to choose $c = 0.9$. Another approach for determining δ_0 sets it to a fixed value regardless of the variability in the reference product. For example, to account for a 30% difference or change in the PD profiles when the maximum (minimum) response is the same for both the test and reference products, set δ_0 at 0.77. A conservative approach is to do both calculations and set

where S_k^2 , $k = R, T$ is the residual variance for the reference and the test product, respectively. If possible, the same subjects should be utilized to obtain information on the PK-PD relationship.

Clinical Efficacy Comparability

To demonstrate that the test and reference products exhibit comparable clinical efficacy, the available data from the historical trials comparing the reference product with placebo (P) and from new clinical comparability studies that directly compare the test and reference products are used. Without loss of generality, we assume the efficacy is measured on some arbitrary scale such that a larger value represents better efficacy. Further, we assume that the summary statistic measuring efficacy can be reasonably assumed to have a normal distribution, where the treatment effect can be measured as a, for example, mean difference between groups (log scale), log-odds ratio, log-relative risk, or log-hazard ratio.

Let γ_{RP} be the true effect of the reference product relative to the placebo and γ_{TR} the true effect of the test product relative to the reference product. Therefore,

$\gamma_{TR} + \gamma_{RP}$ represents the true effect of the test product relative to the placebo. Let B_{RP} and V_{RP} be the estimate of γ_{RP} and the corresponding estimated variance of B_{RP} , respectively, based on a meta-analysis of the data from the appropriate historical clinical trials. Similarly, let B_{TR} and V_{TR} be the estimate of γ_{TR} and the corresponding estimated variance of B_{TR} based on the data from a new comparability clinical trial. Three approaches to assess the comparability between the test and reference products are described below.

Non-inferiority (N) Approach

In this approach, given a margin δ , the goal is to demonstrate the proposed test product is not worse than the reference product by more than δ . The choice of the non-inferiority margin is widely debated in the literature. However, no matter how the margin is selected, for this approach to be valid it must not be larger than the true effect of the reference product relative to the placebo (i.e., δ must be less than or equal to γ_{RP}). One common approach for selecting δ is to pick a value that preserves at least some non-zero fraction, f , of γ_{RP} . This could be based on the lower limit of the 95 percent confidence interval for the reference product relative to the placebo, i.e., $\delta = (1 - f)(B_{RP} - 1.96\sqrt{V_{RP}})$, a common *fixed margin* method and part of the 95-95 approach where the lower limit of a 95% confidence interval for γ_{TR} is compared to this margin. A commonly used value that is referenced as a reasonable starting point for discussion in FDA guidance is $f = 0.5$, i.e., 50% effect preservation.^[41] Thus, the hypotheses for non-inferiority are $H_{01} : \gamma_{TR} \leq -\delta$ vs $H_{a1} : \gamma_{TR} > -\delta$. If a fixed-margin is used, non-inferiority is established if $B_{TR} - 1.96\sqrt{V_{TR}} > -\delta$, i.e.,

$$\frac{B_{TR} + (1 - f)B_{RP}}{\sqrt{V_{TR}} + \sqrt{(1 - f)^2 V_{RP}}} > 1.96 \quad (13)$$

If a *synthesis margin* method is used which also uses the variability information from the current comparability study, then non-inferiority is established if^[42]

$$\frac{B_{TR} + (1 - f)B_{RP}}{\sqrt{V_{TR}} + (1 - f)\sqrt{V_{RP}}} > 1.96 \quad (14)$$

Note that FDA guidance prefers the fixed margin method for the NI approach.^[41] However, it is of interest to note that the left side of these equations will always be larger for the synthesis method (the terms in the denominator are > 0 and $1/\sqrt{A+B} \geq 1/(\sqrt{A} + \sqrt{B})$) and hence the synthesis method is uniformly more powerful than the 95-95 fixed margin approach, or more generally, than any double confidence interval based fixed margin approach provided that the assay sensitivity and constancy are accounted for in order to control the type I error.^[41]

Equivalence Approach

The hypotheses for equivalence are $H_{02} : \gamma_{TR} \leq -\delta$ or $\gamma_{TR} \geq \delta$ vs $H_{a2} : -\delta < \gamma_{TR} < \delta$. If the fixed margin is used, then equivalence is established if $B_{TR} - 1.96\sqrt{V_{TR}} > -\delta$ and $B_{TR} + 1.96\sqrt{V_{TR}} < \delta$, i.e.,

$$\begin{aligned} \frac{B_{TR} + (1 - f)B_{RP}}{\sqrt{V_{TR}} + \sqrt{(1 - f)^2 V_{RP}}} &> 1.96 \quad \text{and} \\ \frac{B_{TR} - (1 - f)B_{RP}}{\sqrt{V_{TR}} + \sqrt{(1 - f)^2 V_{RP}}} &< -1.96 \end{aligned} \quad (15)$$

Using a similar argument as in the non-inferiority case, if a synthesis margin is used, then equivalence is established if

$$\begin{aligned} \frac{B_{TR} + (1 - f)B_{RP}}{\sqrt{V_{TR}} + (1 - f)\sqrt{V_{RP}}} &> 1.96 \quad \text{and} \\ \frac{B_{TR} - (1 - f)B_{RP}}{\sqrt{V_{TR}} + (1 - f)\sqrt{V_{RP}}} &< -1.96 \end{aligned} \quad (16)$$

Constrained Non-inferiority (cNI) Approach

It is a well-known fact that an equivalence approach requires much larger sample size to achieve the same power as the non-inferiority approach. However, the non-inferiority approach only guarantees that the test product is not inferior to the reference product. For the equivalence approach, it is necessary to show that the proposed test product is comparable to the reference product; it has neither decreased nor increased activity compared to the reference product.^[8-10] Hence these two approaches have different merits and concerns. Liao^[43] proposed a constrained non-inferiority (cNI) approach using a similar sample size as the NI approach but also addressing comparability. The cNI approach represents a middle ground where greater evidence is required to demonstrate that the test product is no worse than the reference product (compared to the NI approach) but it is less stringent than the equivalence approach. It properly evaluates that the test product is comparable to the reference product by 1) demonstrating that the test product is not inferior to the reference product and 2) demonstrating that the test shows no increased activity compared to the reference product for the clinical endpoint. If these two objectives are achieved, then the test and reference products are claimed to be comparable.

The proposed cNI approach for claiming comparability depends on two facts. The first is to pass the classical NI requirement to ensure the proposed test product is not inferior to the reference product. The second is to satisfy two constraints: 1) the point estimate of γ_{TR} is within the pre-defined mean boundary and 2) the 95% CI of γ_{TR} is within the predefined plausibility interval to ensure the proposed test product does not exhibit increased activity.

The plausibility interval can be constructed using the idea that any observed difference between the reference against itself should not be considered clinically meaningful, and is defined as $(-k\sqrt{2\sigma_R^2}, +k\sqrt{2\sigma_R^2})$, where σ_R^2 is the total variability for the reference. Liao^[43] used simulation and real datasets to demonstrate that the cNI approach had good performance in terms of power and type I error control. The cNI approach generally requires smaller sample sizes than required for the equivalence approach but still meets all necessary requirements for addressing clinical efficacy comparability.

Incorporating Multiple Batches

Recently, Liao and Yu^[44] presented a very interesting idea by including multiple batches in equivalence and non-inferiority studies to improve the study power. Batch variability exists in almost all products to varying degrees. Generally speaking, more batch variability is expected in biological products than pharmaceutical products. In a clinical study, the drug supply personnel usually buys the product from a single batch, which can be very challenging especially when many companies are vying for the same reference product for many other studies in the same time frame. When using one batch product in a large study with a long study period, there may be a high probability that the product will expire before the end of the study. If there is a large amount of inter-batch variability, a study that uses just one reference batch increases the risk of either not detecting an important effect (low power) or over-stating a statistically significant effect (truth inflation) due to the choice of reference batch used in the study. To overcome this potential risk and reduce the burden of the drug supply department, one straightforward solution is to buy the reference products from different batches manufactured at different times or at different sites/regions. More importantly, at the design stage, increasing the number of batches in the study can increase the study power while controlling the type I error and at the same time reduce the estimation bias of the treatment effect and its variance. The improvement is more significant when the between batch variability is large. Another benefit of using multiple batches is the robustness and reproducibility of the study results. By using more than one batch, the treatment effect is “averaged” and therefore more reflective of true difference. Using more than one batch will also reduce the risk of experiencing a possible clinical supply issue because the reference batch expired.

CONCLUSIONS

Evaluating the comparability of a test product to the reference product is a very complicated task requiring support by many different functional areas (nonclinical, analytical, regulatory, clinical, etc.). Demonstrating comparability

requires a stepwise approach to evaluate the “totality of evidence,” which may include information from structural and functional characterizations, nonclinical evaluation, analytical assessments, human PK/PD studies, clinical immunogenicity studies, and clinical safety and efficacy trials. No one piece of evidence is sufficient to establish comparability or to disprove it. The demonstration of comparability does not necessarily mean that the quality attributes and other key parameters of interest of the reference and test product are identical, but that they are highly similar and that the existing knowledge is sufficiently predictive to ensure that any differences in quality attributes and the key parameters of interest have no adverse impact upon safety or efficacy of the drug product.

In this entry, statistical considerations for evaluating comparability were discussed in the context of analytical testing and human clinical studies (PK/PD, efficacy). The challenges at each phase of the stepwise approach can be different. The criteria for a comparability study should be established at the planning stage with input from relevant subject matter experts. Communication between the sponsor and regulatory agency should begin very early as well. The appropriate design, quality attributes, reference selection, acceptance criteria and statistical methods should all be included in the discussion with the agencies and consensus should be reached prior to beginning the studies. Different agencies may have different opinions on what needs to be completed as part of the overall assessment of comparability. The sponsor should be prepared to design flexibility into their studies to accommodate these potentially differing opinions. To some extent, batch-to-batch variability exists for all products. Because acceptance criteria are often derived based on variability among the reference batches, using too few batches can result in unrealistic criteria that are difficult to meet. It is therefore important and practical to use more than one batch in designing a comparability study for improving the study power. Selecting batches that reflect the likely sources of variability is sensible. How many batches should be used depends on the magnitude of the between batch variability as well as on manufacturing constraints. Due to the complexity of comparability studies, it is recommended that the actual study design and data analysis should be carried out with the close collaboration of a statistician.

All of the discussion has focused on assessing comparability on an attribute-by-attribute basis, including clinical endpoints, if needed. This is somewhat of an abuse of terminology since comparability is a holistic concept, based on the totality of evidence. However, once all of the data have been collected and analyzed, a final overall decision has to be reached. Rarely will the data look so great (or so awful) that the conclusion is obvious. How is the idea of appraising “totality of evidence” implemented in practice? Consider the analytical evaluation of a potential biosimilar. The various assays might be grouped into different categories relating to immunogenicity, quality, process, safety,

etc. At some pre-determined time, such as prior to a key management review, convene a meeting of the relevant subject matter experts to review the data using some sort of scoring system. Calculate a summary measure for each assay category and compare to pre-specified cutoffs. Values above the cutoff increase the likelihood of reaching a comparability conclusion; values below the cutoff decrease the likelihood of reaching such a conclusion. This information is then reviewed with management and a decision is made about the program. As the program moves forward in development, this process can be repeated as new data or information becomes available. This provides a scientifically objective mechanism for making informed program decisions using input from all relevant experts.

Confidence Interval and Hypothesis Testing

Ivan S. F. Chan and Devan V. Mehrotra

Merck Research Laboratories, West Point, Pennsylvania, U.S.A.

Abstract

This entry reviews the general definition and properties of confidence intervals, describes the various methods of constructing confidence intervals including asymptotic and exact procedures, and discusses the duality between confidence interval estimation and hypothesis test.

INTRODUCTION

Parameter estimation is a primary objective in almost every kind of study, whether it is a clinical trial to evaluate the efficacy of a drug or vaccine, a cohort study of excess risk of disease due to toxic exposure, an epidemiological study of disease incidence, or a survey of public opinion. Because of the inherent variability in measurements and study populations, confidence intervals (CIs) are typically used to provide a measure of precision of parameter estimates. The concept of confidence intervals was first proposed by Neyman^[1,2] in the 1930s, and the use of confidence interval has since become an integral part of statistical analyses. In this article, we review the general definition and properties of confidence intervals, describe the various methods of constructing confidence intervals including asymptotic and exact procedures, and discuss the duality between confidence interval estimation and hypothesis test. We emphasize the importance of using the same methodology for confidence interval construction and hypothesis test in order to maintain consistency of statistical inferences.

DEFINITIONS OF CONFIDENCE INTERVALS

In this section we briefly review the general definition of confidence intervals and their properties. More comprehensive discussions can be found in Bickel and Doksum,^[3] Rohatgi,^[4] or Lehman.^[5]

Suppose $(X_1, X_2, \dots, X_n)$ is a random sample from a distribution F characterized by a parameter of interest θ . Let $\theta_L = L(X_1, \dots, X_n)$ and $\theta_U = U(X_1, \dots, X_n)$ be two statistics such that for all possible values of θ

$$\Pr(\theta_L \leq \theta \leq \theta_U) \geq 1 - \alpha \quad (1)$$

Then the random interval $[\theta_L, \theta_U]$ is called a level $(1 - \alpha)$ or a $100(1 - \alpha)\%$ (two-sided) confidence interval for θ . If the parameter θ is r -dimensional, then a confidence

set (or region) can be defined as a r -dimensional space $S = \{\theta: \theta_{Lj} \leq \theta_j \leq \theta_{Uj}, j = 1, \dots, r\}$ such that $\Pr(\theta \in S) \geq 1 - \alpha$ for all θ .

The quantity on the left of Eq. 1 is called the probability of coverage of the interval, and $(1 - \alpha)$ is called the (minimum) confidence level of the interval. If the distribution F is continuous, the equality in Eq. 1 can be achieved; whereas if F is discrete, not all levels $(1 - \alpha)$ are attainable and the confidence interval is generally conservative in the sense that the probability of coverage is at least $(1 - \alpha)$. An interpretation of a confidence interval is that if we perform many experiments (or studies) to evaluate θ and construct a $100(1 - \alpha)\%$ confidence interval based on the outcome of each experiment, then (approximately) at least $100(1 - \alpha)\%$ of these confidence intervals will bracket the true parameter θ .

In some situations, it may be of interest to obtain a lower or upper confidence bound for θ . A statistic $\theta_L = L(X_1, \dots, X_n)$ is called a $100(1 - \alpha)\%$ lower confidence bound for θ if

$$\Pr(\theta_L \leq \theta) \geq 1 - \alpha \quad \text{for all } \theta \quad (2)$$

Similarly, a statistic $\theta_U = U(X_1, \dots, X_n)$ is called a $100(1 - \alpha)\%$ upper confidence bound for θ if

$$\Pr(\theta_U \geq \theta) \geq 1 - \alpha \quad \text{for all } \theta \quad (3)$$

The random intervals $[\theta_L, \infty)$ and $(-\infty, \theta_U]$ are called one-sided $100(1 - \alpha)\%$ confidence intervals. This lower (or upper) confidence bound corresponds to the lower (or upper) bound of an equal-tailed two-sided $100(1 - 2\alpha)\%$ confidence interval.

CONSTRUCTION OF CONFIDENCE INTERVALS

For any given situation, there can be more than one confidence interval at level $1 - \alpha$. In addition, the construction of confidence intervals depends on the choice of statistic used. In general, the length $(W = \theta_U - \theta_L)$ or expected length $(E(W))$ of a confidence interval is used as a measure

of precision. Among all possible $100(1 - \alpha)\%$ confidence intervals based on some statistic T , we desire the one with the shortest length or expected length. However, a uniformly minimum length confidence interval may not exist.^[3] If the distribution of the statistic is symmetric about θ , the expected length of the (two-sided) confidence interval based on the statistic is minimized^[4] by choosing an equal-tailed confidence interval such that

$$\Pr(\theta < \theta_L) \leq \alpha_1 \quad \text{and} \quad \Pr(\theta > \theta_U) \leq \alpha_2, \quad (4)$$

where $\alpha_1 = \alpha_2 = \alpha/2$

The probabilities $\Pr(\theta < \theta_L)$ and $\Pr(\theta > \theta_U)$ are called the left- and right-tail error coverage probabilities, respectively. If the distribution of the statistic is not symmetric about θ , one can find a combination of α_1 and α_2 with $(\alpha_1 + \alpha_2 = \alpha)$ to minimize the expected length. Nevertheless, an equal-tailed confidence interval is often provided in practice for convenience or other considerations.

In many situations the construction of a confidence interval can be based on finding a pivot, which is a function of $(X_1, X_2, \dots, X_n)$ and θ whose distribution is independent of θ . For example, suppose $(X_1, X_2, \dots, X_n)$ is a random sample from a normal distribution with unknown mean (θ) and known standard deviation (σ). A natural (maximum likelihood, minimum variance, unbiased) estimate of θ is the sample mean ($\bar{X}$). Because $\bar{X}$ is normally distributed with mean θ and standard deviation $(\sigma/\sqrt{n})$ the function $\sqrt{n}(\bar{X} - \theta)/\sigma$ has a standard normal distribution (with mean 0 and variance 1) and thus can be considered as a pivot. Therefore, to obtain a 95% confidence interval for θ , we can find c_1 and c_2 such that

$$\Pr(c_1 \leq \sqrt{n}(\bar{X} - \theta)/\sigma \leq c_2) = 0.95 \quad (5)$$

Because the distribution of $\bar{X}$ is symmetric about θ , the shortest confidence interval is the equal-tailed interval with $c_1 = -z_{0.025}$ and $c_2 = z_{0.025}$ where $z_{0.025} (= 1.96)$ is the upper 2.5th percentile of the standard normal distribution. As a result, the 95% confidence interval for θ is $[\theta_L, \theta_U] = [\bar{X} - z_{0.025}\sigma/\sqrt{n}, \bar{X} + z_{0.025}\sigma/\sqrt{n}]$.

When a pivot is not readily available, one may consider using “approximate” pivots based on large sample approximations, and the resulting confidence intervals are usually called asymptotic or approximate confidence intervals. Some examples include the Wilson score confidence interval^[6] for a single binomial probability (θ) based on the (standard) normal approximation of $\sqrt{n}(\bar{X} - \theta)/\sqrt{\theta(1 - \theta)}$, and the approximate confidence interval for the Poisson parameter (θ) based on the (standard) normal approximation of the variance stabilizing transformation $\sqrt{n}(\sqrt{\bar{X}} - \sqrt{\theta})$.^[3] For parameter estimates involving complicated functions of the observed data, simulation techniques such as the bootstrap^[7,8] may be used to construct confidence intervals.

Another common approach to confidence interval construction is to invert a hypothesis test using the duality between hypothesis testing and interval estimation.^[3–5] Such intervals are called test-based confidence intervals. Suppose T is a test statistic for $H_0: \theta = \theta_0$ with size at most α . Let $A(\theta_0)$ be the acceptance region based on T . Then a $100(1 - \alpha)\%$ confidence set for θ based on the observation $(x_1, \dots, x_n)$ is

$$C(x_1, \dots, x_n) = \{\theta_0 : T(x_1, \dots, x_n) \in A(\theta_0)\} \quad (6)$$

A widely used method of constructing test-based confidence intervals is the tail method, which inverts two separate one-sided tests each having size at most $\alpha/2$: one for testing $H_0: \theta = \theta_0$ vs. $H_{11}: \theta < \theta_0$ and the other for testing $H_0: \theta = \theta_0$ vs. $H_{12}: \theta > \theta_0$. Suppose the distribution of T is monotone in θ , and the tail regions in favor of H_{11} and H_{12} are $\{T \leq T_{\text{obs}}\}$ and $\{T \geq T_{\text{obs}}\}$, respectively, where T_{obs} is the observed value of T . Then a $100(1 - \alpha)\%$ test-based confidence interval $[\theta_L, \theta_U]$ can be obtained by solving the two equations:

$$\Pr(T \leq T_{\text{obs}}; \theta_U) = \alpha/2 \quad \text{and} \quad \Pr(T \geq T_{\text{obs}}; \theta_L) = \alpha/2 \quad (7)$$

This tail method is frequently used in constructing “exact” confidence intervals (see, e.g., Clopper and Pearson,^[9] Cornfield,^[10] Santner and Snell,^[11] Zelterman,^[12] Chan and Zhang,^[13] Agresti and Min^[14]). Here the word “exact” refers to fact that the tail probabilities in Eq. 7 are evaluated under the exact sampling distribution of the test statistic. Some approximate confidence intervals such as Wilson’s score interval^[6] for a single binomial proportion and the confidence interval for the difference or ratio of two proportions proposed by Miettinen and Nurminen^[15] can also be considered test-based intervals obtained using the tail method. By construction, the tail method (Eq. 7) yields equal-tailed confidence intervals. If the distribution of T is continuous, then the tail method yields confidence intervals with coverage probability $1 - \alpha$ at all θ . When T is discrete, however, $1 - \alpha$ is the lower bound and thus the confidence interval is generally conservative.^[13,14]

For binomial parameters, Chen^[16] and Agresti and Min^[14] have recently proposed constructing test-based two-sided confidence intervals by inverting one two-sided test for $H_0: \theta = \theta_0$ vs. $H_1: \theta \neq \theta_0$, and showed the resulting confidence intervals are generally narrower than those obtained by inverting two one-sided tests, especially if the underlying distribution is not symmetric. Their confidence intervals preserve the overall coverage probability at $(1 - \alpha)$. However, they are usually not equal-tailed, and thus may not maintain consistency of inference if used in conjunction with one-sided hypothesis test as discussed below.

Table 1 Duality Between Hypothesis Test and Confidence Interval (CI) for Achieving Consistent Statistical Inferences in Comparing Two Treatment Groups Under Different Study Designs

Type of study	Statistical hypothesis on the difference ($\theta = \theta_T - \theta_C$)	Significance level of test	Corresponding criterion for rejecting H_0 based on a test-based CI for the difference θ
Difference	$H_0: \theta = 0$ vs. $H_1: \theta \neq 0$	Two-sided α	Entire two-sided $(1 - \alpha)100\%$ CI excludes 0
Superiority	$H_0: \theta \leq 0$ vs. $H_1: \theta > 0$	One-sided $\alpha/2$	One-sided $(1 - \alpha/2)100\%$ CI lower bound > 0 ; or two-sided $(1 - \alpha)100\%$ CI lower bound > 0
Super superiority	$H_0: \theta \leq \Delta$ vs. $H_1: \theta > \Delta$	One-sided $\alpha/2$	One-sided $(1 - \alpha/2)100\%$ CI lower bound $> \Delta$; or two-sided $(1 - \alpha)100\%$ CI lower bound $> \Delta$
Noninferiority	$H_0: \theta \leq -\Delta$ vs. $H_1: \theta > -\Delta$	One-sided $\alpha/2$	One-sided $(1 - \alpha/2)100\%$ CI lower bound $> -\Delta$; or two-sided $(1 - \alpha)100\%$ CI lower bound $> -\Delta$
Equivalence	$H_0: \theta \leq -\Delta$ or $\theta \geq \Delta$ vs. $H_1: -\Delta < \theta < \Delta$	Two one-sided each at α level	One-sided $(1 - \alpha)100\%$ CI lower bound $> -\Delta$ and one-sided $(1 - \alpha)100\%$ CI upper bound $< \Delta$; or entire two-sided $(1 - 2\alpha)100\%$ CI falls within (to Δ, Δ)

Note: Except for “difference” studies, all two-sided confidence intervals must be equal-tailed in order to maintain the consistency of inference with the corresponding hypothesis tests.

RELATIONSHIP WITH HYPOTHESIS TEST

There is a duality between confidence intervals and hypothesis tests. As described in the previous section, confidence intervals can be constructed based on a hypothesis testing procedure. These test-based confidence intervals are consistent with the hypothesis testing in the sense that both will lead to the same conclusion about the parameter of interest. Similarly, a hypothesis test procedure can be derived from a confidence interval.^[17] Suppose $C(x_1, \dots, x_n)$ is a $100(1 - \alpha)\%$ confidence interval for θ . Consider testing

$$H_0: \theta \in \Omega_0 \quad \text{vs.} \quad H_0: \theta \notin \Omega_0 \quad (8)$$

Then the test that rejects H_0 if and only if $C(x_1, \dots, x_n) \cap \Omega_0$ is a level α test for H_0 .

The duality between confidence intervals and hypothesis tests has a very important implication in making statistical inference. Many studies are designed to test a specific hypothesis, and confidence intervals are routinely provided to quantify the precision of the estimated parameter(s). Based on this duality, one can achieve the same conclusion whether the statistical inference is based on a hypothesis test or the corresponding confidence interval. For example, suppose we are interested in comparing two groups (e.g., test vs. control). Let θ_T and θ_C be the parameters of interest for the test and control groups, respectively, and $\theta = \theta_T - \theta_C$ be the difference between the two groups. Table 1 illustrates the duality between confidence intervals and hypothesis tests that will lead to consistent statistical inferences for comparing two treatment groups based on θ under a variety of study designs. The parameters θ_T and θ_C can be very general, such as the percentages of subjects responding to a treatment, means of some continuous response measures

(on raw or log-scale), log odds ratios, or log hazard rates. The Δ in noninferiority, equivalence, or super superiority studies represents a prespecified, small, positive quantity chosen as the clinically relevant difference or tolerance margin. For equivalence studies, the current recommended (ICH E9 Guideline^[18]) approach of two one-sided tests^[19] is used for the illustration.

CONCLUSION

It is important to note that consistent inferences are maintained only if the same method (such as test statistic or pivot) is used to construct both hypothesis test and confidence interval, or a test-based confidence interval is used in conjunction with the hypothesis test in the same study. For example, in a noninferiority study to compare two binomial proportions ($\theta = \theta_T - \theta_C$), the test statistic proposed by Miettinen and Nurminen^[15] is often used to test the specific hypothesis $H_0: \theta \leq -\Delta$ vs $H_1: \theta > -\Delta$ at the one-sided $\alpha/2$ level. As the Miettinen and Nurminen test uses a constrained maximum likelihood estimate of the variance, a test-based confidence interval using the same constrained maximum likelihood estimation method should be used to ensure the consistency of inference. In this case, a rejection of the null hypothesis at the one-sided $\alpha/2$ level will correspond to the lower bound of the one-sided $(1 - \alpha/2)100\%$ confidence interval, or the lower bound of the two-sided $(1 - \alpha)100\%$ confidence interval, being greater than $-\Delta$. In the case where a two-sided confidence interval is used with a one-sided hypothesis, the confidence interval should be equal-tailed in order to guarantee that the left-tail error coverage probability is $\leq \alpha/2$ and ensure the consistency of inference with the corresponding one-sided hypothesis test.

Confounding and Interaction

Catharine B. Stack

Glenmore, Pennsylvania, U.S.A.

Abstract

Confounding is a bias that must be controlled and something that can be addressed both in the design and in the analysis of a study. Interaction, on the other hand, is an inherent quality of the data, something to be explored once the data have been collected. The aim of this entry is to break down the meaning of these two phenomena and discuss how they are related.

INTRODUCTION

Confounding and interaction, or effect modification, are most commonly discussed in the epidemiological literature. For epidemiological studies, which are generally prospective or retrospective, nonrandomized studies, the principle of confounding is particularly critical. Theoretically speaking, confounding is not a concern for large, randomized studies in the pharmaceutical industry. But often randomizations are not effective in achieving balance across all important prognostic factors, particularly when trials are small or when the number of balancing factors is large. In any event, an appreciation for the issues surrounding confounding can aid in the development of informed study designs. An understanding of statistical interaction is relevant to all studies and is critical to performing meaningful analyses of the data once the trial has been conducted.

CONFOUNDING

Typically, in an epidemiological study, researchers are interested in exploring the relationship between a disease of interest and an exposure, or potential risk factor for the disease. In very basic terms, then, a confounding factor is something that is related both to the exposure and to the disease and that mixes with the exposure to distort the observed association between disease and exposure.^[1–3] A confounder may wholly or partially account for an association between the exposure and disease, or it may mask a true underlying association.

Although confounding results in bias, it differs from other biases, such as selection bias and information bias, in that it is not introduced into a study by the investigators or the subjects. Instead, confounding reflects actual underlying associations between the exposure of interest and the confounding factor and between the disease and the confounding factor. Hence, it is a reflection of the causal associations between variables in the study population.

A hypothetical example will help explain this concept and introduce a discussion of the criteria generally used to assess confounding. Suppose a clinical trial is conducted with 200 subjects and that 100 subjects are randomized to receive drug A and 100 are randomized to receive drug B. The primary outcome of the trial is either success or failure. Overall results are contained in [Table 1](#). These results would indicate that drug A is more effective than drug B because the success rate is 71% for drug A vs. 52% for drug B. Applying a chi-square test of no association to these data results in a p value of 0.006. Results of a more standard epidemiological analysis give an estimated odds ratio, or ratio of odds of success for drug A to that for drug B, of 2.26 with a 95% confidence interval of (1.26, 4.05).

However, when these data are tabulated by the level of a potential confounder or prognostic factor, age (< 70 vs. ≥ 70), a different conclusion emerges. Other examples of possible confounders would be smoking status, gender, previous therapy, and functional status at baseline. [Table 2](#) contains these results broken down by age category. For those subjects under 70, the success rate is 90% regardless of treatment, and for those subjects 70 or older, the success rate is 27% regardless of treatment. Accordingly, the estimated odds ratio is 1 in each strata, with 95% confidence intervals of (0.52, 1.94) for those under 70 and (0.37, 2.69) for those aged 70 and older. Hence, the apparent treatment difference in [Table 1](#) is spurious, due to age, which appears to be a confounder.

Evaluating Confounding

The general criteria used for assessing confounding^[1,3] specify that a confounder:

1. Must be associated with the exposure of interest.
2. Must be associated with the disease or outcome of interest.
3. Must not be a consequence of the exposure or of an intermediate step in the causal pathway of interest.

From criterion 1 we see that an extraneous factor can confound the relationship between treatment and outcome only if it is not evenly distributed in the treatment groups. In regard to the example depicted in [Tables 1](#) and [2](#), criterion 1 requires the proportion of subjects under 70 to differ in the two treatment groups. This criterion is in fact met in this example, because 70% on drug A are under 70 whereas 40% on drug B are in this younger age group.

Similarly, as required by criterion 2, the potential confounder must also be related to the outcome under study. Regardless of how unevenly the potential confounder is distributed in the treatment groups, unless it is also related to outcome there can be no confounding. If the potential confounder is not associated with outcome, there is nothing to mix or add to the association between the treatment and the outcome. In our example, age category, too, is related to outcome, because the success rate among those in the younger age group is 90% as opposed to 27% for those in the older group.

Criterion 3 is most relevant to retrospective epidemiological studies, where study populations are not followed prospectively. For studies in the pharmaceutical industry, this criterion is equivalent to stating that a confounder may not be a postbaseline factor or an intermediate result of the treatment under study. In our example, age certainly is not a consequence of treatment, and age category satisfies all criteria of confounding.

Once a particular risk factor satisfies the criteria for being a confounder, the next step is to evaluate the degree of confounding present. One way to do this is to compare the crude and adjusted estimates of association. For example, an estimated odds ratio calculated from the pooled data may be compared to individual odds ratios calculated within each stratum, or level, of the confounder. Alternatively, the crude estimate of association may be compared to a summary estimate of association that “adjusts” for the

confounder. Methods for finding such adjusted measures of association will be given under the section “Controlling Confounding Through Data Analysis.”

Referring back to our example, we can assess the degree of confounding introduced by age group by comparing the crude odds ratio, 2.26, to the stratum-specific odds ratios, which were both 1. For these hypothetical data, then, one would not want to base conclusions on an unadjusted analysis. The disparity between conclusions made based upon pooled data, as in [Table 1](#), and those made based upon stratified data, as in [Table 2](#), is an effect known as Simpson’s paradox.^[4] In practice, the amount of confounding requiring adjustment is a subjective judgment on the part of the investigator. There is no generally agreed-upon quantitative procedure for determining whether or not a given variable suspected of confounding should be controlled.

Significance tests should not be used to assess confounding.^[1,3] In particular, the *p* values associated with a standard table of baseline characteristics should not be used to determine whether or not a factor is a confounder. The results of these tests are heavily dependent on the size of a study rather than on the degree of confounding present. In addition, for a factor to satisfy the criteria of a confounder it must also be related to outcome. There are no tests able to assess the association of a potential confounder with both treatment group and outcome.

Controlling Confounding Through Design

Of course, the best way to control for confounding is through prevention. All potential confounders should be carefully considered at the time the study is designed. The most effective technique employed in the biopharmaceutical industry to control confounding is randomization. The goal of randomization is to ensure that each eligible subject is equally likely to be assigned to each treatment group. But randomizations are not always perfect. For small clinical trials, an imbalance in one or more prognostic factors is likely, and the resulting confounding can be problematic, given that sample sizes have been estimated assuming a large treatment effect. Even for a very large trial, where profound imbalance in prognostic factors is unlikely, perfect balance is also unlikely, and uncontrolled confounding can potentially affect trial results.^[8]

If a disease outcome under study has known, strong prognostic factors that could act as confounders, then researchers may take additional steps to ensure balance among these factors. One method is through restriction, whereby investigators include only patients with a certain prognostic factor in the trial. Because of the poor generalizability of the results from such a trial, this method may be used only for very small—say, Phase II—trials or in studies where the known relationship between the prognostic factor and disease is much stronger than the expected relationship between the experimental treatment

Table 1 Overall Success and Failure by Treatment

	Success	Failure	Total
Drug A	71	29	100
Drug B	52	48	100

Table 2 Results by Age Category

	Success	Failure	Total
Age < 70			
Drug A	63	7	70
Drug B	36	4	40
Age ≥ 70			
Drug A	8	22	30
Drug B	16	44	60

and disease. For example, in oncology trials, performance status at baseline is highly predictive of outcome. Hence, most cancer trials include some sort of performance level cutoff as part of its inclusion/exclusion criteria.

A stratified randomization might also be employed, whereby treatment assignments are made separately for each stratum, and balance is preserved within each level of the potential confounder. For example, in a study of obesity, where patterns of weight loss may differ by sex, one might chose to stratify by sex to ensure an equal distribution of males and females within each treatment group. Again, such a procedure is effective only for relatively small number of strata, particularly in multicenter trials. When such a stratified randomization is employed, the model used for analysis should still include the stratification factors.

One common method applied in the design of epidemiological studies to control confounding is matching. In a matched study, the investigator intentionally forces the comparison group to have the same or similar distribution as the index group with regard to a potential confounder or confounders. For example, in a retrospective study, controls, or subjects without disease, may be matched to cases or subjects with disease, based upon gender and 5-year age group (e.g., 40–45, 45–50, 50–55). A similar method, called minimization, has been proposed for use in clinical trials.^[5–8] Minimization assigns treatments to subjects sequentially, based upon each subject's individual stratification factors, so that balance may be achieved simultaneously across several prognostic factors. Treatment assignment is made by finding the assignment that “minimizes” imbalance over all prognostic factors considered. This method for assigning treatment is popular for clinical trials in oncology, where there are typically more factors to balance over, such as tumor histology, tumor stage, cell type, prior chemotherapy, and prior radiation.^[8] This method may also be useful for large, multicenter trials conducted internationally.

The primary disadvantage to such a sequential or dynamic assignment scheme is that randomization lists and prepackaged blinded drugs may not be prepared in advance or may not be allocated in numerical sequence. With the advent of telerandomizations and refined Internet communications, however, this method may become more of a practical reality.

Of course, the randomization employed is only as effective as the final comparison conducted. Only those groups assigned by randomization are truly comparable with regard to all potential confounders. Hence, comparing any other groups at the time of analysis defeats the purpose of the randomization. That is, a true intent-to-treat analysis should be conducted whenever possible. For example, bias may be introduced by comparing only those subjects who have completed a study or those with final observations. In such a situation, where final comparison groups differ from the initial groups randomized, methods adjusting for informed dropouts should be investigated.

Controlling Confounding Through Data Analysis

Once a strong confounder has been detected, the simplest way to control for this factor is to perform an analysis within each stratum of the confounder, or by performing a subgroup analysis. By performing such a subgroup analysis, one essentially finds estimates of the association between treatment and outcome, adjusted for the joint effect of the confounders. However, calculating group-specific estimates of association is not the most efficient method of analysis, and often a summary measure across subgroups is required.

Many methods exist for finding point estimates, significance tests, and confidence intervals on summary odds ratios.^[1] The most common method for conducting a test of association while controlling for other factors is to apply a Mantel–Haenszel chi-square test. The Mantel–Haenszel summary odds ratio is a weighted average of the stratum-specific odds ratios, and the Mantel–Haenszel chi-square statistic is used to test a null hypothesis of no association (summary odds ratio = 1). When the direction of association varies across strata, the Mantel–Haenszel test has very little power for detecting departures from no association, and opinions vary on the utility of a summary measure of association. One may choose to assess quantitatively the heterogeneity of stratum-specific odds ratios by applying a test. Again, many such tests exist, such as those proposed by Breslow and Day or Woolf,^[1] although all are unstable when sample sizes within strata are small.

As the number of potential confounders increases or the number of possible levels for a confounder increases, controlling confounding through stratification presents problems unless sample sizes are very large. In this setting, a more unified approach involving the fitting of a linear model with terms for each confounder is preferred. For dichotomous outcomes, such as success rates, a linear logistic model may be used; for continuous outcomes, such as a change from baseline in a laboratory measurement, an ANOVA/ANCOVA model may be employed.

For example, suppose that the outcome under study is a success rate and that x_1 represents treatment ($x_1 = 1$ for drug A, $x_1 = 0$ for drug B) and x_2 through x_p are potential confounders. Performing an analysis that controls for x_2 through x_p involves fitting the linear logistic model:

$$\text{logit}(p) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_p x_p \quad (1)$$

where p is the probability of success and the logit (p) is defined as $\log [p/(1-p)]$. If the outcome is continuous, an analysis that controls for potential confounders involves fitting the ANOVA/ANCOVA model:

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_p x_p \quad (2)$$

where y is the continuous outcome measure.

Strong confounders will impact the estimate of β_1 , and by including them in such a linear model we are able to

find an estimate for β_1 that is adjusted for the confounding factors. For example, comparing the estimate of β_1 from the following models (3) and (4) provides an indication of the degree of confounding introduced by factor x_2 :

$$\text{logit}(p) = \beta_0 + \beta_1 x_1 \quad (3)$$

$$\text{logit}(p) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 \quad (4)$$

Therefore, β_1 as estimated by model (4) may be interpreted as the treatment effect adjusted for factor x_2 . In fact, the logistic regression analysis in model (4) is equivalent to the Mantel–Haenszel analysis presented previously.

When controlling for confounding at the time of analysis, it is important to include all strong confounders, but including factors that have little impact on reducing bias will only increase the variability associated with the estimated treatment effect.^[9] Generally, factors should be included in a model only if they are known from prior studies to be causally related to outcome or if they have been used as a stratifying factor in the design of the trial.

INTERACTION

Interaction is a term referring to a change in the magnitude or direction of the association between treatment and outcome according to the level of a third variable. For example, if a drug is more effective in younger patients than in older patients, there would be an interaction between treatment and age. In this situation, the treatment effect is not independent of age. In the epidemiological literature, this phenomena is often referred to as “effect modification,” because this third variable “modifies the effect” of treatment on outcome. The subtle distinction, however, is that effect modification generally implies causality between the effect modifier and outcome, whereas “statistical interaction” does not.^[10]

Unlike confounding, interaction is not a bias or something that must be controlled in a study. Instead, interaction is something that should be explored so as to gain a greater understanding of the association between treatment and outcome. Interaction is a natural phenomenon occurring in the underlying population from which study participants are selected and will not vary based upon the design of the study.

Evaluating Interaction

An interaction effect is meaningful only within the context of a particular model. Suppose we are analyzing data from a trial with a continuous primary outcome of change from baseline in weight. The variable x_1 corresponds to treatment group (A or B), and x_2 corresponds to gender (male or female). An interaction between treatment and gender may be investigated by fitting the model

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \gamma_1 (x_1 x_2) \quad (5)$$

where y represents the change from baseline in weight and γ_1 represents the interaction term between treatment and gender. If γ_1 is found to be significantly different from 0, then there is evidence of an interaction between gender and treatment, indicating that the effect of treatment and gender on the mean change from baseline in weight is non-additive. In other words, the joint effect of treatment and gender is different from the sum of their independent effects.

Often it is helpful to describe such interactions graphically. Plotting mean changes from baseline by treatment and gender can help in assessing the possible interactions present. For example, Fig. 1a depicts a situation in which the interaction is simply additive, Fig. 1b shows a deviation from an additive interaction in which response to drug B always exceeds that to drug A, and Fig. 1c depicts a situation in which response to drug B exceeds that to drug A in males, but response to drug A exceeds that to drug B in females.

Now suppose that our trial has a discrete outcome of success or failure. An interaction between treatment and gender may be investigated by fitting the model

$$\text{logit}(p) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \gamma_1 (x_1 x_2) \quad (6)$$

where the p is the probability of success and γ_1 again represents the interaction between treatment and gender. If γ_1 is found to be significantly different from zero in this model, we conclude that the relationship between success rate and treatment differs by gender or, using more standard epidemiological terminology, that the effect of treatment and gender on the log-odds for success is non-multiplicative. In other words, the joint effect of treatment and gender on the log-odds for success is different from the product of their independent effects.

For pharmaceutical studies, the interaction terms that are of most interest are those involving the treatment group or dose level. For example, in a dose–response analysis, one might want to examine whether or not the dose–response relationship varies by some third variable. This could be done by incorporating an interaction term in the model and evaluating its impact on model fit. Or, in a large, multicenter trial, one might want to test for a treatment-by-center effect.

Interaction terms including only prognostic factors are most useful in controlling interrelated confounding effects. In terms of analysis, it is recommended that one first consider and evaluate potential confounders, and then incorporate any interactions present. This order of analysis is recommended because the primary aim of most analyses is to assess the relationship between outcome and treatment, and including interaction terms with treatment while assessing confounding complicates this determination.

Fig. 1 (a) Additive interaction between treatment and gender. (b) Nonadditive interaction between treatment and gender in which response to drug B always exceeds that to drug A. (c) Nonadditive interaction between treatment and gender in which response “changes direction”

REGULATORY REQUIREMENTS

Regulatory guidelines do not specifically address the principle of confounding, but they do discuss the need for randomization in the design of clinical trials. Section 2.3.2 of the current version of the *Guideline on Statistical Principles for Clinical Trials*, proposed by the International Conference on Harmonization,^[11] discusses the role of randomization in clinical trials. These guidelines cite randomization as one of the critical techniques that should be adopted so as to provide “a sound statistical basis for the quantitative evaluation of the evidence relating to treatment effects.” In addition, the ICH recommends stratifying

on study center and other important prognostic baseline factors, particularly in small studies. Dynamic allocation procedures are discussed and advocated only after careful consideration of “the complexity of the logistics and potential impact on the analysis.”

Section 5.7 of ICH9 addresses the use of covariates, or possible confounders, and interaction terms in the data analysis. The guidelines stress the importance of “prestudy deliberations” concerning the potential covariates affecting outcome and advise that potential confounders be included in the analysis plan whenever possible. They also suggest, “when the potential value of an adjustment is in doubt, it is often advisable to nominate the unadjusted analysis as the one for primary attention, the adjusted analysis being supportive.”

In the discussion of interaction, the ICH guidelines recommend prespecification of any planned subgroup or interaction analyses in the analysis plan, adding that “in most cases, however, subgroup or interaction analyses are exploratory and should be clearly identified as such.” They go on to caution that “any conclusion of treatment efficacy (or lack thereof) or safety based solely on exploratory subgroup analyses are unlikely to be accepted.”

CONCLUSION

Confounding and interaction are different yet related phenomena. Confounding is a bias that must be controlled and something that can be addressed both in the design and in the analysis of a study. Interaction, on the other hand, is an inherent quality of the data, something to be explored once the data have been collected. A prognostic factor may be both a confounder and an interaction term, one of these, or neither. Confounding must be assessed qualitatively; interaction may be tested more quantitatively.

When designing a study, the most effective approach to block confounding is to employ randomization. To reduce further the possibility of confounding for known strong potential confounders, study subjects may be restricted by the level of the potential confounder, or a stratified or sequential treatment assignment may be followed.

When analyzing the results of a study, unexpected confounding can be controlled by fitting linear models with terms for such factors as well as any stratification factors used in the design of the study. Such a model may also be used to explore any interactions with treatment, or differences in treatment response based upon the level of another variable.

At some level, the goal of every study is to assess the true association between treatment and outcome. Control of confounding improves the estimate of this underlying association. Identification of treatment interaction terms may affect product labeling and prescribing, in the later phases of research, or may assist in targeting populations for further research, in the earlier stages.

Content Uniformity

John R. Murphy

Eli Lilly and Company, Indianapolis, Indiana, U.S.A.

Abstract

Content uniformity is a measure of the variation in the amount of active ingredient from one dosage to the next. This entry is concentrated on the process and importance of formal dose uniformity tests and discusses the different factors that can present problems in content uniformity of drug dosages.

INTRODUCTION

Content uniformity is a measure of the variation in the amount of active ingredient from one dosage to the next. In a perfect world, every dosage unit would contain exactly the same amount of drug. However, in the real world of manufacturing tablets, capsules, or other final dosage form, the active drug substance is diluted with excipients to mask taste, to enhance bioavailability, to add bulk, or to promote stability. In such processes, it is not always possible to obtain absolute homogeneous mixing of the drug with the excipients. Factors such as different densities, different particle sizes, and different particle shapes contribute to different settling tendencies and flow characteristics, which may cause slight variations in the amount of active ingredient present in the dose-sized partitions of the batch. Even if absolute homogeneity in the formulated drug product can be obtained, uniformity of active ingredient content in the final dosage forms would still not result because it is not possible to fill every capsule or to compress every tablet to contain exactly the same weight of drug product. In order to achieve adequately homogeneous mixtures of bulk drug product, manufacturers validate the mixing process with respect to time and other mixing parameters. However, even with a validated process, it is still necessary to explicitly demonstrate adequate content uniformity in the final dosage units on a batch-by-batch basis. This is usually carried out with a formal dose uniformity test.

OVERVIEW

All three major pharmacopeias, the United States Pharmacopeia and National Formulary (USP/NF),^[1] European Pharmacopeia (EP),^[2] and the Japanese Pharmacopeia (JP)^[3] have formal criteria for judging the uniformity of dosage units. While the tests are somewhat similar, there are important differences that can lead to cases where a product sample might meet the requirements of one test but not the criteria of the other. [Table 1](#) provides a

side-by-side comparison of the requirements of the three pharmacopeia. The reader will note that the wording in [Table 1](#) is different from the descriptions of the test given in the applicable pharmacopeia. This has been performed in order to facilitate comparison of the tests. Inspection of the three tests shows that the criteria in both the USP and the JP tests are tied to the mean content, in addition to controlling the allowable variation from the mean, while the EP deals only with the variation in the content of individual units from the mean content.

Although these tests should not be confused with a sampling and acceptance plan for lot release with respect to content uniformity, their performance can be evaluated using operating characteristic (OC) curves, which provide the probability that the test will be passed versus the hypothesized true mean and relative standard deviation (RSD) of the product. [Figs. 1–3](#) show the OC curves for the three compendial tests for a range of true means and RSD values. The curves can be generated using Monte Carlo simulation. As illustrated in [Fig. 1](#), when the true mean content is near 100% of label claim, the JP test and both USP tablet and capsule tests behave similarly, while the EP test is different. In [Fig. 2](#), where the true mean is less than 100%, the JP test is less likely to be passed than the USP tests because it places more emphasis on deviations from 100% of label than the USP. The OC curves of the EP are nearly the same as before because the operating characteristics are mostly unaffected by changes in the true mean content. [Fig. 3](#) illustrates the provision of the USP for cases when the rubric mean (average of the potency limits) is more than 100%. Here the JP is much tighter than the USP and EP because it employs similar treatment for deviations in both the high side and the low side of 100%. In these cases, the USP is seen to perform in a middle ground between the JP and the EP. Other cases of interest could be generated and examined in this way through the use of simulations and OC curves.

In the near future, pharmacopeial harmonization will lead to more common global compendial criteria. The tests for uniformity of dosage units is slated for harmonization,

Table 1 Requirements of the Three Major Pharmacopeia

	USP/NF	EP	JP
Sample sizes	10 + 20	10 + 20	10 + 20
Definition of M	M = greater of $\bar{X}$ and 100% and lesser of $\bar{X}$ and rubric mean	$M = \bar{X}$	$M = 100\%^a$
Capsules, etc.	$n1 = 1$ and $n2 = 3$	$n1 = 1$ and $n2 = 3$	–
Tablets, etc.	$n1 = 0$ and $n2 = 1$	$n1 = 0$ and $n2 = 1$	–
Stage 1	Pass: $n \leq n1$ and $RSD \leq 6.0\%$ and $m = 0$ Fail: $n > n2$ or $m > 0$	Pass: $n \leq n1$ and $m = 0$ Fail: $n > n2$ or $m > 0$	Pass: $\bar{X} - 2.2s \geq M - 15\%$ and $\bar{X} + 2.2s \leq M + 15\%$ and $m = 0$ Fail: $m > 0$
Stage 2	Stage 2: $n1 < n \leq n2$ Pass: $n \leq n2$ and $RSD \leq 7.8\%$ and $m = 0$ Fail: $n > n2$ or $m > 0$ or $RSD > 7.8\%$	Stage 2: $n1 < n \leq n2$ Pass: $n \leq n2$ and $m = 0$ Fail: $n > n2$ or $m > 0$	Stage 2: Neither pass nor fail Pass: $\bar{X} - 1.9s \geq M - 15\%$ and $\bar{X} - 1.9s \leq M + 15\%$ and $m = 0$ Fail: $m > 0$ or $\bar{X} - 1.9s < M - 15\%$ or $\bar{X} + 1.9s > M + 15\%$

Rubric mean = average of potency limits in the monograph; n = number of assays outside 85–115% of M; m = number of assays outside 75–125% of M; RSD = relative standard deviation.
^aUnless otherwise specified in the individual monograph.

Fig. 1 Operating characteristic curves for current JP, USP, and EP when rubric mean = 100% and actual mean = 100%

Fig. 3 Operating characteristic curves for current JP, USP, and EP when rubric mean = 104% and actual mean = 104%

Fig. 2 Operating characteristic curves for current JP, USP, and EP when rubric mean = 100% and actual mean = 96%

and the next few years should see a single compendial test for uniformity of dosage units that is applicable to products in most major markets of the world. It is a natural extension of the concept of content uniformity to ask whether a simpler and more straightforward measure of variability, such as RSD, would be more appropriate for judging compliance. Even if the location of the mean content is kept in the equation, criteria similar to those in the JP have appeal because they are analogous to statistical tolerance limits. In such case, the criterion for passing the test is that there be a given level of confidence that a sufficiently high proportion of the dosage units fall within, e.g., 85–115% of label.

The expectation that content uniformity will be maintained throughout the shelf life of the product leads to the question of whether a manufacturer would have product

release criteria different from the pharmacopeial tests. By using the OC curves of the compendial tests, one could compare a candidate release criterion to see how it compares with the official test. Another way the OC curves of the compendial tests can be used is to determine the likelihood that the compendial requirements will be met for a product where the mean content and the variation of content is known. Bergum^[4] developed methods for determining acceptance limits for the sample mean and standard deviation that give a specified probability that the USP will be met. Sampson et al.^[5,6] examined alternate ways to assess content uniformity by exploiting the relationship between weight and content of the dosage unit, and they proposed sampling and acceptance strategies that could be used for product release.

CONCLUSION

In summary, content uniformity is an important product quality attribute that provides the patient assurance that no matter which tablet or capsule is taken, an acceptable amount of active drug will be delivered. Manufacturers perform validation to demonstrate that the mixing and finishing operations produce uniform dosage units with

respect to the content of active ingredient. Where applicable, batches are tested for content uniformity prior to release to provide assurance that the product will comply with compendial standards of uniformity. Currently, different compendial requirements are applied in different parts of the world, but international harmonization of the tests for uniformity of dosage units is under way.

Continual Reassessment Methods

Xue Lin

US Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Abstract

This entry introduces the Continual Reassessment Methods and its variations.

Keywords: Continual Reassessment Methods; Bayesian; Phase I clinical trials; dose escalation.

INTRODUCTION

In the drug development process, a drug usually needs to go through a series of clinical trials to show its efficacy and safety. And the first step in this process is usually to find a safe and efficacious dose. Phase I studies are usually for this purpose.

It is often assumed that as dose increases, the drug becomes more efficacious, however, at the same time, its toxicity increases too. The maximum tolerated dose (MTD) is the most efficacious dose with an acceptable safety profile. And safety is usually assessed by the frequency of dose limiting toxicity (DLT) occurrences.

Before the continual reassessment method was introduced in 1990 by O’Quigley, Pepe et al.,^[1] the so called “3+3” design was widely used to find the MTD. As the name indicates, in this design, cohorts of 3 subjects are treated at a dose level, and depending on the toxicity outcome, additional 3 subjects may be treated at the same dose level, or at a higher dose level. A detailed discussion of the “3+3” design can be found in^[2]. The “3+3” design was criticized for its inefficiency when the drug toxicity is over-estimated and its lack of transparency in the targeted toxicity rate^[1].

Besides “3+3” design, there are other methods for dose escalation. Simon et al.^[3] proposed to use the accelerated titration design in Phase I oncology trials. This study design used inpatient dose escalation and thus efficiently escalated the dose to the target level. Collins et al.^[4] proposed to use the real-time PK measurement to guide the dose escalation.

THE CONTINUAL REASSESSMENT METHOD

The general idea

The continual reassessment method is a Bayesian method. The general idea of this method is illustrated in Figure 1.

Figure 1 shows 5 doses. Each dose has a prior probability of DLT as shown in the left panel where the 95% credible interval is represented by a line segment at each dose. The horizontal dotted line represents the target DLT probability, which is 30% in this example. Once the trial begins and toxicity information accumulates, the prior belief on DLT probability gets updated, which results in the posterior distribution as shown in the right panel.

The prior DLT probability distributions at each dose level are different but are assumed to have the same parametric form and are functions of the corresponding dose level. Subjects enter the trial sequentially and the toxicity information on a subject is used to update the model parameter. The next subject will be treated at the dose level whose mean or median DLT probability is closest to the target probability.

The original CRM

The original continual reassessment method (CRM) was proposed by O’Quigley, Pepe et al.^[1] This section describes CRM, but first we will introduce some notations.

Suppose there are K dose levels denoted as $(d_1, d_2, \dots, d_K)$, Y_j is a binary variable defined as

$$Y_j = \begin{cases} 1, & \text{if the } j\text{th subject has DTL} \\ 0, & \text{otherwise} \end{cases} \quad j = 1, \dots, N$$

Let $p(d, \alpha)$ be the dose-toxicity function where d is the dose level and α is the unknown model parameter. And we require that $p(d_i, \alpha)$ equals the probability of DLT at dose level d_i , $i = 1, \dots, K$. The goal of the trial is to find the dose level whose mean probability of DLT is closest to the target γ .

Suppose the prior distribution of α is $p_0(\alpha)$. The likelihood function for the first j subjects are the following

$$L(Y_1, Y_2, \dots, Y_j | \alpha) = \prod_{i=1}^j p(d_i, \alpha)^{Y_i} [1 - p(d_i, \alpha)]^{1-Y_i}$$

Fig. 1 Prior and posterior probability of dose limiting toxicity (DLT). The two figures show the general idea of Bayesian dose escalation method

Using Bayes' Theorem, we can get the posterior distribution of α as

$$\Pr(\alpha | Y_1, \dots, Y_j) = \frac{p_0(\alpha) * L(Y_1, Y_2, \dots, Y_j | \alpha)}{\int p_0(\alpha) * L(Y_1, Y_2, \dots, Y_j | \alpha) d\alpha}$$

With the updated (posterior) distribution of α , the posterior mean probabilities of DLT at each dose level are as the following

$$\theta_{i,j} = \int p(d_i, \alpha) \Pr(\alpha | Y_1, \dots, Y_j) d\alpha \quad (i = 1, \dots, K)$$

Then a dose level is chosen to minimize the distance to the target DLT probably γ as

$$\arg \min_{i=1, \dots, K} \Delta(\theta_{i,j}, \gamma)$$

where Δ is a distance function such as absolute difference. Then the $(j+1)$ th subject will be treated at this chosen dose level.

To ease the computational burden, the authors also offer alternatives to the direct calculation of $\Delta(\theta_{i,j}, \gamma)$. Instead one could calculate the posterior mean of α and plug it in the dose-toxicity function $p(d, \alpha)$, then find the d_i that minimize the distance between $p(d_i, \alpha)$ and γ , or back calculate d that produce the target DLT probability γ and then find a dose level d_i that is closed to the d .

Widely used dose-toxicity functions are hyperbolic function ($\{(\tanh(x) + 1)/2\}^a$), logistic model ($\frac{e^{2+ax}}{1+e^{2+ax}}$) and power model ($X^{\exp(a)}$).

MODIFIED CRM (mCRM)

Goodman^[5] proposed modifications to the original CRM. The major modifications are as follows:

- Instead of starting with the dose whose prior mean DLT probability is the target DLT probability, always starts with the lowest dose.

- Only escalate to a dose that is one level higher when the algorithm recommends a dose that is more than one level higher
- Treating at least 3 subjects at each dose level instead of 1 as CRM proposed

These modifications to the CRM are out of consideration of safety. Along the same line of thinking are the modifications proposed by Faries^[6] and Piantadosi and Fisher.^[7]

AN EXAMPLE OF mCRM

We illustrate how mCRM works via a simulated trial. We will use Goodman's version of the mCRM method.

Suppose the trial tests 5 dose levels: 10 mg, 50 mg, 75 mg, 100 mg and 125 mg, and their associated DLT probabilities are 5%, 15%, 30%, 45%, and 60% respectively. The target DLT probability is 0.30.

We choose the power model for the dose toxicity function:

$$p(d, \alpha) = d^{\exp(\alpha)}$$

For the prior distribution of α , we choose the Gamma distribution with both parameters equal to 1: $p_0(\alpha) = \text{Gamma}(1, 1)$

The prior distribution of DLT probabilities at each dose level is in Figure 2.

The first three patients enter the trial and they are treated at the lowest dose level which is 10 mg. The subjects' DLT outcomes are simulated from the true toxicity probability, which is 5%, and none of the first three subjects have DLT.

Fig. 2 Prior DLT distribution at each dose level for the simulated trial

Based on the toxicity outcome of these three subjects, the distribution of the dose-toxicity function parameter α is updated and we have a posterior distribution of K . The probability distribution of DLT at each dose level gets updated accordingly. Panel 1 of Figure 3 shows the posterior probability of DLT at each dose level after the toxicity outcome of the first cohort is available.

Although dose level 3 has a mean DLT probability closet to the target 30%, with mCRM, there is no dose skipping, so the next cohort of three subjects are treated at the dose level that is one level higher than the current dose, i.e. dose level 2.

And in the same way, the DLT probability is updated depending on the toxicity outcome for this second cohort and the algorithm recommends a dose level for the next cohort of subjects. Figure 3 shows how the posterior DLT probability distribution at each dose level continuously updated after each cohort of subjects are treated.

When the trial's stopping criteria is reached, which is at least 6 subjects have been treated at the recommended

dose level and a total of 18 subjects have been treated in the trial, the trial stops and the algorithm recommends dose level 3. And this dose level is then the MTD dose chosen and will be used for future Phase II trials.

EXTENSIONS OF CRM

There have been numerous extensions of the original CRM method. The original CRM assumes that drug toxicity monotonically increases as the dose increases. This monotonicity may be compromised in various clinical situations. Thall and Cook^[8] extended CRM to situations where both toxicity and efficacy are considered in dose finding. And Wages, Conaway and O'Quigley^[9] extended CRM to multi-agent trials in which only a partial order of toxicity can be assumed. In the original CRM methods, the dose-toxicity function is assumed and could be mis-specified. In addressing the uncertainty in the dose-toxicity function, Yin and Yuan^[10] proposes the Bayesian Model Averaging

Fig. 3 Posterior DLT probability distribution at each dose level continuously updated after each cohort of subjects are treated

CRM (BMA-CRM). Their simulation study shows that BMA-CRM is robust to misspecification of the dose toxicity function and its improvement over CRM is prominent when the dose toxicity function is mis-specified by large amount.

DISCUSSION

Due to safety concerns, the modified CRM methods are often used in clinical trials instead of the original CRM method. Usually when a trial implements the CRM method or its variants, the operating characteristics of the method needs to be studied via simulation. The simulation needs to include various dose toxicity settings, the method's performance needs to be evaluated on aspects such as, the chances that the right dose is chosen, the proportion of subjects treated at each dose level, especially the percentage of subjects treated at the dose levels whose DLT probability are higher the target DLT, etc.

SOFTWARE

The MD Anderson cancer center has a software Kiosk (<https://biostatistics.mdanderson.org/softwaredownload/>) which provides computer software implementing the CRM and several of its variations. The CRM is also available in R as a package.

Contract Research Organization (CRO): Early 2000s

T. Y. Lee

Independent Consultant, Morristown, New Jersey, U.S.A.

Abstract

The contract research organization has become an important partner to pharmaceutical and biotechnology companies in the development of new compounds. This entry reviews the history and growth of the CRO and touches on its future in the pharmaceutical industry.

INTRODUCTION

Over the years, the pharmaceutical industry has developed a full-scale capability to carry out research from laboratory discovery to biological screening, animal toxicity studies, formulation, clinical pharmacology, stability, clinical trials, new drug applications (NDAs), and promotional marketing. During the late 1970s to early 1980s, the return of investment was so great that little attention was paid by the industry to the reaction of the consumer. Research and development (R&D) costs for the pharmaceutical industry have been doubling every 5 years since 1970; the average cost of bringing a drug to market was \$125 million in 1989 and climbed to \$231 million in 1993.^[1] “It was not unheard of for a potential shortfall in profitability to be remedied simply by a rise in product prices.”^[2] Although prescription drug prices have risen an average of 2.3 times faster than consumer prices since 1980,^[3] the probability of developing a successful drug is very small. According to the Center for the Study of Drug Development at Tuft's University, of every 5000 compounds that are synthesized, just five will enter clinical trials and just one will be approved by the Food and Drug Administration (FDA). As R&D costs increased steadily in the late 1970s, the use of contract research organization (CRO) has become very popular for handling tasks specific to pharmaceutical research and development, especially the conduct, data management, and statistical analysis of clinical studies.

INDUSTRY BACKGROUND

Pressures on the Pharmaceutical Industry from the Early 1990s

The funds from drug development has been decreasing, especially for the high-risk biotechnology products. For biotechnology companies, access to capital was drying up during the early 1990s and was continuing to do

so under the impact of health-care reform. In 1991, biotech companies raised \$6.5 billion; however, in 1992, just \$5 billion was raised. The value of the industry's stock fell 6% to \$45 billion, a loss of \$1.4 billion, while R&D expenses rose 14% to \$5.7 billion.^[4]

1. *Pricing Pressures.* While drug prices continued to outgrow the consumer price index, the public became discontent with the cost of drugs, hospitalization, doctors, and insurance. In early 1990, 37 million Americans lacked coverage for health insurance. In the meantime, the influx of generic drugs, the therapeutic substitution, and the reduction of tax credits for studies designed for marketing purposes have given the pharmaceutical industry a wake-up call. To counter the criticism of ever-rising health-care costs, health-care providers and insurance companies have formed their own respective super large organizations to consolidate their buying power for pharmaceuticals and health services. These powerful health maintenance organizations (HMOs) demand deeper price-cuts from the drug companies. In addition, the government demands rebates on sales to Medicare patients, who are the high-volume users of prescription drugs. Congressman Henry Waxman (D, California) stated, “If we are serious about controlling health-care costs, we must address the issue of prescription drug prices. Congress, as part of health reform, must find a way to balance profits and prices in a way fairer to the American consumer.”^[5]
2. *R&D Cost Increases Faster Than Price.* Despite the pricing pressure (or perhaps because of it), the pharmaceutical industry has continued to increase spending on R&D. The top 30 companies spent \$20 billions on R&D in 1993, representing 18.3% of sales, while 1994 sales grew by only \$6 billion.^[6] R&D costs have been nearly doubling every 5 years since 1970; and the average cost of bringing a drug to the U.S. market rose from \$125 million in 1989

to \$231 million in 1993 (just a little over 4 years). It cost an average of \$450 million to develop a new drug in 1997.

Alternate Approaches to Pharmaceutical Research and Development

In order to stay competitive and to maintain a healthy profit margin, pharmaceutical companies have adopted various approaches to respond to the pressures:

1. *Downsizing and early retirement.* As of July 1993, the pharmaceutical industry had already lost 18,000 jobs (according to the Pharmaceutical Manufacturers Association (PMA)). Many companies offered early retirement packages to reduce the workforce.
2. *Out-licensing nonmajor products.*
3. *Merger and consolidation.* Numerous pharmaceutical companies merged to expand their product lines. Once such mergers were consummated, the layoffs and early retirements followed. Companies that merged during this period included: SKF and Beecham, Dow and Merriam, Eastman Kodak and Sterling Drug, AHP and A.H. Robins, Merck and Johnson and Johnson Joint Venture, Hoffman LaRoche and Genentech, Merck and DuPont Joint Venture, Rh'one-Pulenc and Rorer, Bristol-Myers and Squibb, Roche and Syntax, AHP and American Cyanamid.
4. *Comarketing.* The sales forces of different companies are joining together to penetrate the market and to expand market share. For example, Glaxo Holding PLC worked with Roche on Glaxo's Zantac using Roche's 800-strong sales force. Smith Kline Beecham and DuPont comarketed SKB's Tagamet. Beecham and Upjohn joined forces to sell Beecham's heart-attack drug Eminase.
5. *Developing only the drugs with potential major market shares.*
6. *Developing one's own generic business.* Hoechst brought 51% of Copley Pharmaceuticals for \$546 million, which is 20 times Copley's 1992 sales of \$51.9 million. Merck established a separate generic house, West Point Pharma, to compete with manufacturers of generic drugs.
7. *Developing an over-the-counter (OTC) market that was not under the price limit.* Warner-Lambert and Wellcome PLC formed a joint venture to comarket OTC drugs.
8. *Price-cut to expand market shares.* Merck's Mevacor is an example of the vulnerability of products that enter crowded therapeutic classes. A 1 month's supply of Merck's Mevacor 20 mg was \$60 in April 1994. Sandoz launched Lescol 20 mg with a sale price of \$30/mo, which was less expensive than both Merck's Mevacor and BMS Pravachol (\$54/mo).
9. *Giving up research.*
10. *Farming out R&D to contract research organizations (CROs).* This accelerates R&D without tying up the internal resources of the pharmaceutical companies. To bring a product to market 1 month earlier would generate \$10 million in sales if the product had annual sales of \$120 million, and \$50 million in sales if the product had annual sales of \$500 million. It also brings in know-how in a new therapeutic area quickly. The CRO unit can be used as an independent quality control arm.

EMERGENCE OF THE CONTRACT RESEARCH ORGANIZATION INDUSTRY

Contract Research Organizations in the Public Market

As R&D costs increased steadily in the late 1970s, a few service organizations emerged to handle specific tasks for the pharmaceutical companies such as identifying investigator sites, monitoring, data processing, statistical analysis, report writing, and regulatory supports. By the mid-1980s, G.H. Besselaar, for example, had grown to several hundred employees to provide an almost full range of services to the pharmaceutical industry. By the late 1980s and early 1990s, pressure from the health-care reform forced pharmaceutical companies to staff at trough and to use CROs to supplement their resource need. The outsourcing of clinical research needs to CROs was established as a branch service industry when G.H. Besselaar was acquired by Corning Glass works in 1989.

Research and Development Spending and Duration of Marketing Exclusivity

Despite cost containment, pharmaceutical companies have continued to increase their spending on R&D, which exceeds \$35 billion/yr.^[7] The reasons for the continued elevation of R&D costs are numerous. The number of the NDAs increased from 3233 patients in 1985–1988 to 3567 in 1989–1992, and to 3936 patients in 1993–1996.^[8] The number of procedures per patient also increased from 256 in 1992 to 319 in 1993, to 331 in 1994, and to 372 in 1995.^[9] One of the reasons for the increased number of procedures is the globalization of drug development, which in turn increases the complexity of the regulations on clinical trials. The improved efficiency created even more pressures on competitors to market the new drugs faster. Therefore, the number of years of exclusivity enjoyed by the pharmaceutical companies have been reduced drastically.^[10] Inderal was approved in 1968 and enjoyed marketing exclusively for 10 years. Tagamet was approved in 1977 and had 7 years of exclusivity. The other

major drugs' approval dates (duration of exclusivity) were as follows:

Capoten	1980	(5 yr)
Prozac	1988	(4 yr)
Diflucan	1990	(2 yr)
Recombinant	1992	(1 yr)
Invirase	1995	(0.25 yr)

The pressure from generic-drug producers has never reduced. Brand-name drugs typically lose 70% of their market share at the end of the first year following the introduction of the generic version. Therefore, utilization of CROs becomes a strategic decision.

GROWTH OF THE CONTRACT RESEARCH ORGANIZATION INDUSTRY

Increase of Outsourcing by Pharmaceutical and Biotechnology Companies

As of the end of 1997, the annual spending on R&D by pharmaceutical and biotechnology companies had exceeded \$35 billion. Two-thirds of this spending (approximately \$22 billion) was devoted to clinical research. The CRO industry was awarded approximately \$2.5 billion and is expected to grow 10% a year.

Full-Service Contract Research Organizations Grow Rapidly

Full-service CROs are growing rapidly due to the following reasons:

1. The incentives for drug firms to outsource clinical testing.
2. The continued expansion of biotechnology research.
3. The greater clinical testing requirements being imposed on medical device manufacturers.
4. Market share gains resulting from industry consolidation.
5. The rewards conferred on the first product to market.

Pharmaceutical companies are beginning to recognize the advantages of developing broad as well as deep relationships with a limited number of vendors. CROs able to service the full continuum of R&D needs have the following capabilities:

1. A broad range of therapeutic expertise in designing clinical trials.
2. The ability to efficiently collect, analyze, and manipulate data from many patients with various clinical conditions across many geographically dispersed sites.

3. The ability to provide a full range of trial management services to customers who wish to narrow their relationships to a limited number of CROs for drug development activities.
4. The ability to conduct trials at diverse geographical sites, allowing simultaneous filings of registration packages in several major jurisdictions.^[11]

Upstream and Downstream Growth of Contract Research Organizations

By the end of 1994, there were more than 200 Drug Information Association (DIA)-registered CROs in the United States,^[12] and a similar number of CROs were established in Western Europe. To stay competitive, the wider range of services is an important incentive for the CROs to attract pharmaceutical clients. Starting in 1996, the CRO industry realized that it needs more diversification from the traditional clinical monitoring, data processing, statistical analysis, and regulatory support. The leading CROs ventured upstream into central laboratory, drug-packaging, and health-economic services. Starting in 1996, large CROs brought contract sales service organizations. "Although there have been moves to harmonize product registration and requirements, nevertheless, it is still a multidomestic market with different medical rules, regulations, laws, and medical practices in every country."

Some other CROs acquired organizations that provide prelaunch product strategy services, tactical sales, and reimbursement support services. Some CROs invested in companies that specialized in combinatorial chemistry and functional genomics. To accelerate the recruitment of patients for clinical trials, companies with calling centers became the target of acquisition in 1997 and 1998.

FUTURE OF THE CONTRACT RESEARCH ORGANIZATION INDUSTRY IN THE PACIFIC RIM

Market Size for Pharmaceuticals

The Japanese pharmaceutical market is about \$55 billion/yr, or 20% of the world market, with an annual growth rate of 10%. "Until recently, there was little recognition of the need for CROs, in Japan."^[14] The Ministry of Health, Labor and Welfare (MHW) has established a study group (Honma Group) to review the need for CROs in Japan. The Honma Group supports the use of CROs in Japan if they are properly controlled. CRO groups are being established by various multinational CROs.

The need for CRO support in Taiwan to conduct clinical trials is evidenced by the presence of multinational CROs in recent years. A similar need for CROs is observed in Australia, Southeast Asia, India/Pakistan, Eastern Europe, and Latin America.

Critical Issues to Ensure the Quality of Clinical Trials

Critical issues to ensure the quality of clinical trials include the following:

1. *The attitude of medical professionals.* In most Pacific Rim countries (except China), medical professionals enjoy a special social status. The CRO monitors have to deal with the attitude of "I am a doctor and I know what I am doing. Don't come here to tell me what I have to do." Investigators with this type of attitude tend to generate case reports with a higher percentage of errors.
2. *Informed consent.* It will require great effort to educate both investigators and patients that clinical research cannot be done without the proper protection of the rights of the patients. The language of informed consent should be balanced and should be understandable by the local participants.
3. *Transparency of budgeting and payment.* Each budget item should be clearly identified and accountable and should reflect the needs of local trials.
4. *Respect for intellectual property.* Respect for intellectual property will encourage multinational companies to conduct more clinical trials in this region.
5. *Time availability of the investigators and coordinators.* Investigators in some research institutes have very limited time to do research. Their understanding of the efforts required to conduct well-controlled clinical trials is not compatible with the actual time required.
6. *Simplifications of the governmental approval process.* The approval process should be independent of the relationship between the sponsor and governmental officials. The approval process should also be transparent to the public.
7. *Affordable central laboratories.* In the near future, the clinical data from Asia will routinely be part of the multinational submission. The cost of data generated from the Asia-Pacific Rim should be proportional to the local cost of living.

Extension of Traditional Contract Research Organization Services

Traditionally, pharmaceutical and biotechnology companies treat R&D and sales and marketing as their core value and as proprietary. They guard and manage them with in-house employees. In 1997, a major shift in the FDA policy toward direct marketing by pharmaceutical companies to the potential consumer was announced. This policy shift opens a new avenue for CROs to provide contract sales services (contract sales organizations (CSOs)) to pharmaceutical and biotechnology companies. The growth of contract

sales is expected to accelerate, and the mergers of CSOs will probably intensify in the coming years.

Although CROs have ventured upstream to acquire discovery and research arms, such as combinatorial chemistry, functional genomics, and special assays, the future of such services is not clear. As site management organizations (SMOs) have continued to grow in number, to consolidate, the experience of mixing CROs and SMOs has not been very impressive.

To accelerate pharmaceutical development, information technology (IT) is critical to the efficient processing of data. More CROs are acquiring firms that provide the technology to enhance integrated information processing, real-time status, information sharing, and global data harmonization. The IT services in this field will grow; however, the development and maintenance cost are high and the success rate is usually low.

CONCLUSION

The CRO has become an important partner to pharmaceutical and biotechnology companies in the development of new compounds. The CRO has also provided services in drug registration. The total spending on R&D by pharmaceutical and biotechnology companies is estimated to exceed \$35 billion. Two-thirds of this is spent on clinical trials, and the CROs have captured only 10% of this. Of the top 20 pharmaceutical companies, 19 have invested in emerging markets such as China, India, Russia, and Latin America. These markets are accessible to clinical research for fast patient enrolments because of the improvement in adopting the practice of the International Conference on Harmonization (ICH) and Good Clinical Practices (GCPs). The large CROs have been following the path of pharmaceutical companies into the Asia-Pacific market since 1996. The Asia market for CROs will expand rapidly in the next 10 years. Therefore, the potential for further growth for traditional CRO is enormous. Originating in 1997, the CRO has acquired marketing and sales capabilities to extend services downstream. The estimate for worldwide marketing and sales expenses (\$36 billion) is very close to worldwide R&D spending. If growth of the traditional CROs is any indication of the potential growth of contract sales and marketing (CSOs), then the growth and consolidation of CSOs will be accelerated. Larger players from other industries may join in to capture the growth. The traditional nature of CROs has changed, and they will evolve into a formidable industry.

Contract Research Organization (CRO)

Tamara Pinkett

Biostatistics, IQVIA, Durham, North Carolina, U.S.A.

Jill Dawson

Corporate Communications Consultant, Danville, California, U.S.A.

Abstract

A contract research organization (CRO) is a company or organization that contracts with pharmaceutical, biotechnology, and medical device companies to assist in their research and development processes. This article highlights the purpose, history, and growth of CROs. This article is an overview of the services provided by the CRO with a focus on the role of the biostatistician within a CRO.

INTRODUCTION

Pharmaceutical companies continue to face pressure due to factors such as health-care cost containment efforts, patent expiries, optimizing patient access to acutely needed drugs, and rising research and development (R&D) costs. Contract research organizations (CROs) have evolved to help address these pressures. A CRO is a company or organization that contracts with pharmaceutical, biotechnology, and medical device companies to provide specialized services to assist in their R&D processes.

The CRO marketplace originated in the 1940s and 1950s and started to emerge in its present form in the late 1970s and the early 1980s.^[1] Today's CROs range from small, niche specialty groups to large, international full-service organizations. In this diverse industry, the top 10 CROs represent more than half of the world market, with the rest divided between 700–1,000 small and mid-sized companies.^[2]

A decade ago, the primary role of CROs was to run clinical trials. On average, it takes at least 10 years to bring a drug to market and costs about USD 2.6 billion,^[3] with several thousand compounds being explored in drug discovery in order to develop one approved drug. Drugs being developed are moved through a series of phases. Typically, this is divided into three phases, with a fourth phase being postapproval investigations. In the United States, before any clinical trials involving human subjects can be initiated, an Investigational New Drug (IND) application must be submitted to the U.S. Food and Drug Administration (FDA). After the IND application is submitted, the FDA typically has 30 days to reject the application; if the FDA does not reject it, approval is automatically granted.

Phase 1 trials involve 20–100 healthy volunteers, last for several months, and are conducted to evaluate the candidate drug's safety and appropriate dosing. Approximately

70% of drugs move to the next phase. Phase 2 trials involve up to several hundred people with the disease or condition, last usually for several months to 2 years, and are executed to investigate the efficacy and side effects of the drug. About 33% of drugs move to Phase 3 trials, which involve 300–3,000 volunteers who have the disease or condition, generally last for 1–4 years, and are performed to evaluate efficacy and monitor adverse reactions.

Around 25%–30% of drugs move to the next phase. At this point, a New Drug Application (NDA) can be submitted, triggering the regulatory review of the nonclinical and clinical data. If the data indicate that the drug has sufficient benefit to outweigh its risks, the FDA will approve the product for commercial sales, but may require additional clinical trials to evaluate populations not investigated before approval or to monitor the safety of the compound in the wider population in which the drug will be prescribed. These studies would be executed in what is known as Phase 4 of clinical development. Phase 4 trials involve several thousand volunteers who have the disease or condition and are conducted to further evaluate the safety and efficacy of the drug. The types of services a CRO may provide through the product life cycle are shown in Table 1.

Today, as sponsor organizations become ever leaner, they are partnering with CROs to gain access to skill sets, including broad therapeutic expertise, that are no longer available in-house. Additionally, in the last decade, as biopharmaceutical drug developers has shifted the activities from North America and the European Union to regions in Asia such as India, China, and Korea, they have used CROs to expand their global reach. Full-service partnering and portfolio management, including joint strategic decision-making, and expanding from the clinical realm into the commercial one, is becoming more widespread, driving growth in the CRO market.

Table 1 Examples of services a CRO may offer

Clinical Solutions and Services	
Project management and clinical monitoring:	Late phase and advisory services:
• Clinical data management • Study design and operational planning • Investigator/site recruitment • Site and regulatory start-up • Clinical monitoring • Project management • Digital patient services	• Product development strategy consulting • Regulatory and compliance consulting • Process and IT implementation consulting
Clinical trial support services:	Commercial services:
• Clinical data management • Biostatistical services • Central laboratories • Bioanalytical laboratories • Cardiac safety and ECG laboratory services • Safety and pharmacovigilance operations • Phase I clinical pharmacology units	• Contract sales • Market entry/market exit • Integrated channel management • Patient engagement services • Market access and commercialization consulting • Brand and scientific communications • Medical education
Strategic planning and design:	Outcome/observational:
• Biomarkers, genomics, and personalized medicine • Model based drug development • Planning and design • Regulatory affairs services	• Observational studies • Product and disease registries • Comparative effectiveness studies • Payer/provider solutions

Zion Research predicted in June 2017 that the world-wide CRO market would reach USD 59.42 billion in 2020, increasing at a compound annual growth rate of 9.8% between 2015 and 2020.^[4] Industry Standard Research projected in March 2017 that the market would grow at an average annual rate of 6.8% from 2016 to 2021^[5]; and Grand View Research Inc. forecast in January 2016 that the CRO industry would reach USD 45.2 billion by 2022.^[6]

The regulatory space continues to evolve at a rapid pace, with CROs offering particular expertise and access to regulatory opinion due to their broad range of activities for many clients in many therapeutic areas. Regulators are increasingly accepting novel study design alternatives, such as adaptive trial designs, which use accumulating data to evaluate efficacy more efficiently and precisely in particular populations, drawing on cumulative experience, and master protocols, which allow multiple drugs to be evaluated in the same trial. Adaptive designs have forced CROs to be more flexible in their trial designs, since the demand for adaptive designs has been growing at approximately 35% per year over the last decade.^[7] These designs have required more continuous data monitoring, use of Data Monitoring Committees on a more regular basis, and greater statistical expertise. Another area of growth has been in real-world evidence, where data are analyzed from electronic health records, surveys, and other sources.

Among the opportunities for collaboration between biopharma companies and CROs are the potential to

- **Increase predictability** by creating study plans based on evidence, in order to mitigate operational risks, reducing the number of protocol amendments and increasing the likelihood of regulatory approval.
- **Shorten timelines** by using historical data to select appropriate sites, reducing the number of low- and non-enrolling sites, improving the predictability of enrollment rates, and reducing the time to last patient in.
- **Maximize asset value** by basing development decisions on real-world insights and analytics to generate relevant evidence earlier in the process. This can help optimize coverage and reimbursement, and reduce the time to peak sales.

THE ROLE OF THE BIOSTATISTICIAN WITHIN A CRO

Biostatisticians apply statistical methods to drug development in many areas including methodology, modeling pharmacokinetics, bioequivalence and bioavailability testing, monitoring product safety, and product quality assessment.^[8] Within CROs, biostatisticians are involved in every step of clinical research including trial design,

protocol development, data management and monitoring, data analysis, and clinical trial reporting.^[9] The importance of this role is demonstrated by the fact that the largest CROs may employ as many as 1,000 biostatisticians across 10 or more countries.

There are multiple differences between the business models of CROs and pharmaceutical companies (see Table 2). This is reflected in differing roles for statisticians. In CROs, statisticians typically work in a variety of therapeutic areas across all phases of trials, whereas in pharma companies, they tend to work in one therapeutic area, usually concentrating on one particular phase of development.

Biostatistical services span all study phases and therapeutic areas, including work on clinical development plans, protocols, case report forms, statistical analysis plans, and data analysis and interpretation. Biostatisticians also provide support for clinical study reports and for regulatory submissions; they may also attend meetings with regulators and offer expert testimony. Additional examples of roles are shown in Table 3.

At CROs, expert-level biostatisticians are used for such tasks as the following:

- Clinical development plans and other strategic program planning, such as NDA planning
- Protocol development

- Consulting on complex design or analysis issues
- Methodology development
- Internal review of all tables, study reports, and text
- Expert testimony (i.e., statistical theory, regulatory requirements/expectations)

Another interesting area of expert-level biostatistical input may include personalized medicine. For example, recent developments in mobile health include health-related mobile web applications for providers and potentially for patients. Applications include personalized dosing to target drug exposure via population pharmacokinetic models and randomized concentration-controlled trials. On June 16, 2017, FDA commissioner Dr. Scott Gottlieb announced an FDA initiative to accelerate the approval of mobile web applications.^[10]

At CROs, there are typically two key roles within biostatistics. First, are the statisticians, who typically have a master's degree or doctorate in statistics, biostatistics, or a related discipline. The biostatistician acts as the overall biostatistical team lead and project contact, and the role involves planning the study and data analyses, coordinating the production and review of data analyses and outputs, drafting or reviewing the clinical report, and interacting with the customer. Second, are the statistical programmers, who have extensive SAS programming skills. The primary

Table 2 A comparison between pharmaceutical companies and CROs

Pharmaceutical companies vs CROs	
Pharmaceutical companies	CROs
• Discover and own drugs • Responsible for all aspects of drug development from early phase through to marketing and packaging • Statisticians tend to work in one therapeutic area, usually concentrating on one particular phase of development	• Do not “own” drugs • Large CROs offer full service, getting involved in all aspects of drug development from early phase through to marketing and packaging • Statisticians work in a variety of therapeutic areas across all phases of trials • Offer cost containment (supplement existing work force), speed, international drug development, experience, specialized services

Table 3 Biostatistical services in CROs

Services		
• Clinical development plans • Protocol and data collection tool development • Statistical analysis plans including table shells • Analysis interpretation and reporting (analysis datasets, tables, listings, graphics) • Data Monitoring Committee support • Patient profiles	• Standardized dataset (CDISC) authorized supplier • Clinical study report support • Regulatory submission (e.g., IND, NDA, sNDA, MAA, BLA, and CTD) • Feasibility analysis • Nonclinical analysis • Regulatory representation • Expert testimony • Modeling and simulation	• Monitoring optimization • Prescription to over-the-counter switch trials • Postmarketing manuscript support • Fraud detection • Pharmacogenomics • Consultancy • Adaptive clinical trials • Biomarkers • Flexible resourcing models

CDISC = Clinical Data Interchange Standards Consortium; sNDA = supplemental New Drug Application; MAA = Marketing Authorization Application; BLA = Biologics License Application; CTD = Common Technical Document.

responsibilities of this role include developing programs to produce statistical analyses and outputs, verifying programs, and carrying out independent verification for all analytical outputs. Either role requires that person to be very detail-oriented. Depending on the CRO, the disciplines may be performed by different staff or be combined into one role.

ACKNOWLEDGMENTS

The authors thank Dr. Russell Reeve for his helpful discussion about the advances in pharmaceutical research and development, the demand for CROs, and the role of the (bio)statistician.

Abstract

This entry aims to clarify the role of *p*-values in hypothesis testing by examining methods for dealing with multiplicity, discussing various testing principles, and providing methods of analysis.

Keywords: Clinical trials; Evidence; Multiplicity; Null hypothesis; *P*-value.

INTRODUCTION

Multiplicity is widespread in clinical trials and is of increasing concern because many trials now aim at multiple objectives of different regulatory and scientific importance. Potential sources of multiplicity in trials include comparison of several dose groups, investigation of treatment effects for multiple endpoints observed at multiple time points, superiority and non-inferiority tests, subgroup analysis, variable and model selections, and analysis for demographic factors and for targeted regions in multi-regional trials. These and other sources of multiplicity in a trial can make the traditional α -level (e.g., at $\alpha = 0.05$ or 0.01) statistical tests and evaluations for various objectives of the trial not necessarily valid. That is, multiplicity in a trial can increase the likelihood of finding some treatment effects by chance alone, in the absence of no such treatment effects. If the probability of such chance findings, traditionally known as false-positive or type I error rate, is inflated in a trial due to multiple testing then such a trial is said to have a multiplicity problem. Solutions for this problem can generally be found when holding to some key statistical principles, methods, and clinical ideas, which are the focus of this article.

The remainder of this article is organized as follows: in the first few sections we clarify concepts of inferential *p*-values, “substantial evidence,” and “replication,” as these concepts relate to proper interpretation of results of a trial in the context of robustness of evidence and multiplicity of findings. Subsequent sections cover multiplicity concept, familywise error rate and its control, commonly used methods for addressing multiplicity, multiple hypotheses testing principles, and multiplicity considerations for some clinical trials. This article is intended for those interested

in the design, conduct, analysis, and interpretation of results of controlled clinical trials.

P-VALUE AND ITS MEANING

Clinical trial publications extensively report *p*-values as evidence of positive findings. If a *p*-value is small, it is taken as evidence against the so-called “null hypothesis” of no treatment effect, and subsequently for claiming a treatment effect. Such statistical evidence is often confused with the regulatory term “substantial evidence,” which is a much broader concept used in the regulatory decision-making. We will clarify these concepts, as understanding the concept of substantial evidence in relation to the statistical evidence may help in better planning of a single or multiple trials for a given indication.

Within the hypothesis-testing framework, the definition of *p*-value is straightforward but its interpretation is not. *p*-value is different from the type I error rate that is pre-specified, even though both use tail areas under the null hypothesis distribution of the test statistic. Its value is not known until the experiment is over. Suppose that a vector $\mathbf{y}$ represents observed measurements on an endpoint in an adequate well-controlled trial, and $T(\mathbf{y})$ is a value of the test statistic $T(\mathbf{Y})$, which is a statistical measure of the treatment effect, such as *t*-test or a log-rank statistic. Let δ be an unknown parameter of the treatment effect, such that values of $\delta \in \Omega_0$ are not desirable to the experimenter and he/she wants to rule it out. For example, if δ is the true treatment difference defined as the true cure rate by the new treatment minus the true cure rate by the control treatment, then $\delta \leq -\Delta$ means that the new treatment is inferior to the control by a tolerable margin of Δ . Similarly, if this

$\delta \leq 0$, this means that the new treatment is not more efficacious than the control. These δ values are then in Ω_0 , which are counter to what the experimenter desires to conclude from the experiment. A p -value associated with the null hypothesis H_0 : $\delta \in \Omega_0$ is then defined as the probability that $T(\mathbf{Y})$ is “more extreme” than the observed $T(\mathbf{y})$ given that H_0 is true. Here “more extreme” is in the direction against the null hypothesis.

This p -value is a routine statistical measure of uncertainty used in all kinds of scientific and medical experiments to date, and is taken as a measure of evidence against the null hypothesis if it is small, for example, less than 0.05. The approach taken in this regard is the method of contradiction.^[1–3] That is, assume that the null is true and show that the observed data conflict with this assumption. The smaller the p -value, the greater is the degree of this conflict, thereby giving greater support to the idea that the null hypothesis is not true.

The p -value as defined above is a random variable, uniformly distributed over the $[0, 1]$ interval under the null hypothesis. This distribution property under the null hypothesis is true regardless of whether a given study is small, large, highly powered, or underpowered. This property has led to the use of a cutoff point of p -value, such as 0.05, for claiming evidence against the null, meaning that the chance is 1 in 20 that an experiment with no treatment effect would result in a p -value of 0.05 or less. This error rate is known as the type I error rate in the context of the Neyman-Pearson theory of hypothesis testing.^[4] It is easy to show that this type I error rate is much higher than 0.05 if multiple null hypotheses were tested simultaneously without any statistical adjustments for multiplicity.^[5,6]

However, it is important to recognize that a small p -value could also arise in an experiment which has nothing to do with the evidence against the null hypothesis. An unusual problem or property of data at hand can give rise to a small p -value. Randomization and blinding techniques in clinical trials protect results from bias, but despite these measures, there are often problems. For example, in chronic disease areas and prevention trials, patients are usually treated and observed for longer periods, resulting in dropouts. A p -value claiming a treatment effect in this situation may be confounded by informative dropout effects depending on the extent of dropouts. Also, clinical trials that do not analyze all randomized patients may lose validity of inference that randomization provides, and even if all randomized patients were included, an imputation technique used for missing data may have failed to preserve the natural course of the disease and variability in the data. In addition, the sampling distribution of the statistic $T(\mathbf{Y})$, because of unusual behavior of the data, may be flat-tailed, having a larger p -value than that calculated by a generic standard formula. Furthermore, clinical trials often exhibit multiplicity issues missed at the design and analysis stages, and hence leading to questionable p -values.

Despite the above concerns, the p -value, when appropriately calculated, validated, adjusted for multiplicity, and properly interpreted, does provide evidence against the null hypothesis if it is small. The smaller the p -value, the greater is this evidence. In using a p -value, however, an important point to know is that it is not a probability of the null hypothesis, as misunderstood by some. It is rather a measure of the degree of the conflict of the data with the null hypothesis, producing a result only when this measure of conflict for a given data exceeds a pre-specified level.

Evidence based on the p -value approach is often called a “frequentist” approach for making inference. There are other approaches. Bayesian and the “likelihood” approaches are the main ones. The Bayesian approach requires specifying a model for the sampling data as the likelihood function $L(\mathbf{y}|\theta)$ conditional on parameters θ , as well as a prior distribution on θ . This setup considers the parameters as random variables and all inferences use the posterior distribution, which is the distribution of the parameters θ , conditional on the observed data. In contrast, the frequentist approach considers sampling observations as a random sample and parameters as fixed unknown quantities. The likelihood approach utilizes the likelihood function for making inference, justifying that once the sample data is observed, the likelihood function contains all necessary information about the unknown parameter θ . There have been arguments about these inference procedures claiming advantage of one over the other by citing special examples. However, we feel that a p -value that is derived from a sufficient test statistics and for which the test is constructed by the Neyman-Pearson likelihood ratio principle is quite appropriate for making inference for many controlled clinical trials.

EVIDENCE AND REPLICATION

The concept of evidence for making regulatory decisions has been around for sometime.^[7–9] It includes, in addition to statistical evidence, evidence from other areas, including epidemiology, basic sciences, ethics, and good clinical practices. Another concept embedded in the regulatory standard is the concept of replication. This implies that the collective evidence derived from multiple studies or in special cases from a single study should be reliable and reproducible with high probability. This replication probability idea is a valuable concept for assuring that a claimed result of treatment effect when clinically interpretable is a persuasive result.

The Kefauver-Harris amendment of the Food, Drug, and Cosmetic (FDC) Act of 1962 defined the concept of “substantial evidence” for the effectiveness of the drug in Section 505(d) of the Act as “evidence consisting of adequate and well-controlled investigations.” This has been interpreted in general to imply at least two adequate well-controlled confirmatory studies (as defined in 21 CFR

Table 1 Conditional and Posterior Predictive Probabilities of Finding a Statistically Significant Result at the 0.05 Significance Level in a Second Study for Various Observed p -Values in the First Study

Observed p -value (1st study)	0.05	0.025	0.01	0.005	0.0025	0.001	0.0005
Conditional power method	0.50	0.61	0.73	0.80	0.86	0.91	0.94
Bayesian predictive probability method	0.50	0.58	0.67	0.73	0.77	0.83	0.86

314.126), each convincing on its own as evidence of efficacy of a new drug. The justification for such a requirement is the need for independent substitution of experiments often referred to as the need for replication of the findings.^[8,9]

Thus, the requirement for substantial evidence has been interpreted to go beyond observing evidence from a single trial for the purpose of providing further assurance by requiring replication of study findings. The concept of replication is intended to provide additional assurance of the efficacy of the drug to be used for the patient population after weighing against possible safety risks. A large, well-designed, and adequately powered multi-center study with small p -value is expected to provide stronger evidence than a small study with p -value close to 0.05. Thus, in special situations, one might consider findings of such a large study with a small p -value (e.g., $p < 0.001$) as having established the substantial evidence sought, as long as this result is internally consistent and clinically meaningful. To account for such situations, for example in difficult disease areas where it might be unethical to do a second study, the U.S. Congress amended Section 505(d) of the Food, Drug, and Cosmetic Act by issuing Section 115(a) of the Food and Drug Administration Modernization Act (FDAMA), which states that the Agency in special situations may consider “data from one adequate and well-controlled clinical investigation and confirmatory evidence” to constitute substantial evidence. Useful discussions about the two-study versus single-study evidence can be found in Koch^[10] and Huque^[11] published as commentaries to a paper by Shun et al.^[12]

Following Goodman,^[13] the probability of replicating a statistically significant result in a second study depends on the true treatment effect size. On assuming that the true treatment effect size is the same as the observed treatment effect size in the first study, the probability of replicating efficacy for a second (would-be-conducted) study is simply the conditional power for this effect size. Mathematically, suppose that d_1 is the observed treatment difference for the first study and z_1 its corresponding treatment difference value on the normal Z -scale, then the probability of replicating a significant level α result in a second future trial is given by $\Pr\{|Z_2| > z_{\alpha/2} | \theta = z_1\}$, where Z_2 is the test statistic for this second study, θ being the true treatment effect size on the Z -scale, and $z_{\alpha/2}$ is the cutoff point such that the tail area under the standard normal density curve from $z_{\alpha/2}$ to infinity is $\alpha/2$. This probability of replication is then given by $\Pr\{|Z_2| > z_{\alpha/2} | \theta = z_1\} = 1 - \Phi(z_{\alpha/2} - z_1) + \Phi(-z_{\alpha/2} - z_1)$, for $z_1 \geq z_{\alpha/2}$.

Such a probability of finding a statistically significant result in a replicated experiment can also be calculated by the predictive probability approach of Geisser.^[14] Suppose that the posterior probability density of θ , using a flat prior, is $p_1(\theta | z_1) = N(\theta; z_1, 1)$ and the probability density of the second to-be-replicated trial is $f_2(z_2 | \theta) = N(z_2; \theta, 1)$. Then the posterior predictive probability density of Z_2 given z_1 is

$$f(z_2 | z_1) = \int_{-\infty}^{\infty} f_2(z_2 | \theta) p_1(\theta | z_1) d\theta = \frac{1}{2\sqrt{\pi}} \exp\left\{-\frac{1}{4}(z_2 - z_1)^2\right\} \\ \sim N(z_1, \sqrt{2})$$

Table 1 displays probabilities of finding a statistically significant result at the 0.05 significance level in a second identical study for various p -values observed in the first study by the above two approaches. These results show that a p -value of 0.05 found in a single experiment is not persuasive evidence, as the probability of replicating this result in a second study is only 50%. It is only when the p -value in the first study is less than 0.001 that one would expect a probability of 85% or greater for finding a result statistically significant in a second study. Note that the posterior predictive probabilities in Table 1 are consistently smaller than conditional probabilities when observed first-study p -values range from 0.0005–0.025.

MULTIPLICITY CONCEPT

A clinical trial that may not have any multiplicity issue has two groups, one with the treatment and the other a control group, and has a single clinical endpoint of importance, such as mortality, that can characterize a meaningful benefit of the test treatment. This is the case of testing a specified single null hypothesis of a single clinical endpoint without any interim analysis. However, even for this simplest case, as the data used is the sample data of this endpoint, its outcomes have associated uncertainties due to sampling variations. As a result, a positive treatment effect comparison result can appear with certain probability due to chance alone when in reality there is no such treatment effect. This error probability is called the *false-positive error rate* or the *type I error rate*. By convention, the type I error rate, also called alpha (α) usually is set at 0.05 (i.e., 5% or 1 in 20). This means that there is a 5% chance that results as extreme as those observed in the trial could have occurred by chance alone. It also means that if the investigator performed 20 similar trials, one of them might yield

a false-positive result. The type II error results from concluding that there is no treatment effect when in fact there is a treatment effect; in other words, it is a false-negative result. In the language of hypothesis testing this is accepting the null hypothesis when in fact the null hypothesis is false. The *type II error* rate, also called beta (β), is usually set at 0.10 or 0.20 (i.e., 10% or 20%). Power is defined as $100 \times (1 - \beta)\%$ and is correspondingly set at 90% or 80%.

The above simple case is based on the premise that there is one treatment comparison in order to answer one research question on a single endpoint. However, trials in general are rarely that simple. Many trials now aim at multiple objectives of differing regulatory and scientific importance, and usually test more than one research question or perform treatment comparisons on more than one endpoint at more than one time point. Consequently, the potential to draw a false positive conclusion, that is, the type I error rate, may increase. The trial may have the opportunity to win for treatment effect in multiple ways. This is analogous to taking a black box filled with 19 white marbles and one black marble, and asking a volunteer to choose one marble from the box at random blindly. The probability of choosing the black marble by chance is one in twenty, or 5%. On the other hand, if one increases the number of black marbles in the box, say, on keeping the same total 20 marbles in the box, the likelihood of choosing a black marble by chance increases. As one increases the number of black marbles in the box, the likelihood of pulling a black marble out by chance continues to increase. In other words, there are multiple ways to achieve a successful outcome in this situation. This example illustrates the issue of multiple testing or *multiplicity* that is, testing more than one treatment comparison or hypothesis or endpoint in a single trial.

Potential sources of multiplicity in trials include comparison of several treatments or dose groups, investigation of treatment effects for multiple endpoints measured at multiple time points, superiority and non-inferiority tests with interim analyses, subgroup analysis, variable and model selections, and analysis for demographic factors and for targeted regions in multi-regional trials. These and other sources of multiplicity in a trial can make the traditional α -level (e.g., at $\alpha = 0.05$ or 0.01) statistical tests and evaluations for various objectives of the trial no longer valid. That is, multiplicity in a trial can substantially increase the likelihood of finding some treatment effects by chance alone, in the absence of no such treatment effects. This phenomenon, which increases the frequency of chance findings, is traditionally known as the *inflation of the type I error rate*. A trial design is said to have multiplicity issues when it faces such an inflation of the type I error rate in conducting multiple statistical tests.

For example, if the probability of finding a significant result by chance is 0.05 in making a single comparison, then the unadjusted probability of finding a significant result by chance can be as high as 0.23, 0.40, 0.64, and 0.92 in

making 5, 10, 20, and 50 comparisons, respectively. These calculations follow from $1 - (1 - 0.05)^m$ with m being the number of independent comparisons made each at level $\alpha = 0.05$. These are substantial increases in the type I error rate compared to 0.05, i.e., 1 in 20 times. In this case, application of statistical approaches to adjust the results for multiplicity generally becomes necessary in order to control for the chance of erroneous conclusions. However, it is worth noting here that there are clinical trial situations that do not raise multiplicity issues even though the trial may perform multiple statistical tests. A few of these cases are covered in the section “Clinical Decision Rules.” An example is the testing for co-primary endpoints in a trial, which requires that each specified endpoint demonstrate treatment efficacy for characterizing a clinically meaningful benefit of the treatment.

FAMILYWISE ERROR RATE AND ITS CONTROL

In statistical testing of a family of multiple null hypotheses when the interest is to reject at least one of them for a treatment effect, a commonly used error rate is the familywise error rate usually denoted by the acronym FWER or FWR. This is a generalization of the usual type I error rate for a single hypothesis testing problem to multiple hypotheses testing problems. Consider testing m multiple (null) hypotheses $H_1, \dots, H_m$, where some hypotheses may be true and some may be false but their true status are unknown. This uncertainty gives rise to a total of $2^m - 1$ combination of true and false hypotheses as *null hypothesis configurations*. Suppose that for an arbitrary null hypothesis configuration, one calculates the probability of committing at least one type I error. Then this probability is called the familywise error rate (FWER) for that configuration. A test procedure is said to “control” FWER at level α for a specific null hypothesis configuration if FWER for that configuration is less than α .

A null hypothesis configuration of special interest is the one in which all m null hypotheses are assumed to be true null hypotheses. Such a null hypothesis configuration is often called a *global* or a *complete null hypothesis*. This is also referred to as an *intersection null hypothesis* of dimension m . If a test procedure controls FWER at a specified level α (e.g., $\alpha = 0.05$) only for the global null hypothesis then it is said to control FWER *weakly* at that level. However, if a multiple hypothesis testing procedure controls FWER at level α for all possible null hypotheses configurations, that is, for all possible combinations of true and false null hypotheses, then it is said to control FWER *strongly* at that level.^[5] Often FWER control is meant FWER control in the strong sense if there is no ambiguity.

In testing multiple (null) hypotheses $H_1, \dots, H_m$, often the interest is in making inference about the individual hypotheses H_j for each $j = 1, \dots, m$. This is achieved by controlling FWER at level α for all possible null hypotheses

configurations, including the global null hypothesis. As an illustration, consider a two-arm cardiovascular trial for assessing the effect of a new therapy against a control for three primary endpoints: all-cause mortality, stroke, and myocardial infarction (MI). The clinical interest for this trial is in making endpoint specific claims of efficacy of this therapy. The investigator then seeks to find the effect of the new therapy individually for each of these three endpoints. In this case, there are a total of seven null hypothesis configurations for making endpoint specific inferences, and one needs to control FWER for all these seven null hypotheses configurations. Therefore, this case requires strong control of FWER.

COMMONLY USED METHODS FOR ADDRESSING MULTIPLICITY

There are many statistical methods tailored for different situations that control FWER strongly. They can be broadly classified into two types: single-step and multi-step procedures. Single-step procedures that control FWER strongly and provide adjusted p -values, also easily offer adjusted confidence intervals for the magnitude of the treatment effects. On the other hand, multi-step procedures generally preserve the power of the tests more efficiently, but their adjusted p -values do not easily convert to adjusted confidence intervals. In the following, Bonferroni and Šidák procedures are single-step, whereas Holm's and Hochberg procedures are multi-step. Multi-step procedures have been of two types, *step-down* and *step-up* procedures. In step-down procedures, one starts with the smallest p -value (i.e., the most significance test) and then steps-down to the next smallest p -value (i.e., the next most significance test) and so on. In contrast, step-up procedures proceed in the reverse direction. They start with the largest p -value (i.e., the least significant test) and step-up to the second largest p -value and finally to the smallest p -value (i.e., the most significant test). In the following section, we briefly discuss the Holm's procedure as an example of a step-down procedure and the Hochberg procedure as an example of a step-up procedure. The subsequent section reviews some commonly used single and multi-step procedures for addressing multiplicity in clinical trials, starting with simple ones.

Bonferroni Test

The Bonferroni test is a single-step procedure and is a commonly used test for the primary objectives of clinical trials, as it works under all correlations and joint distributions of the test statistics. The procedure applies directly to p -value of the individual hypothesis tests when a given family of m hypotheses to test, and reliably and conservatively controls FWER in the strong sense. The Bonferroni test is simple to apply. One chooses positive weights $w_1,$

$w_2, \dots, w_m$ for the m individual hypotheses H_j (for $j = 1, \dots, m$) according to some clinically meaningful criteria (e.g., by the clinical importance of the m hypotheses) with the sum $(w_1 + w_2 + \dots + w_m) \leq 1$, and calculates weight adjusted values $q_j = p_j/w_j$, where p_j is the observed p -value on testing H_j in the trial. One then rejects H_j for those $j = 1, \dots, m$ for which $q_j < \alpha$. For simplicity of application it is customary to take equal weights $w_j = 1/m$. With these equal weights one rejects H_j for any j when $p_j < \alpha/m$.

Holm's Test

The Holm's^[15] test is a step-down procedure, and like the Bonferroni test, it is a commonly used method for the primary objectives of a trial. Similar to the Bonferroni test, it provides FWER control in the strong sense for all types of correlations among test statistics and their joint distributions. It can be implemented with weights as well as without weights. In the unweighted Holm's test, one orders the p -values of the individual m hypothesis tests in increasing order as $p_{(1)} \leq p_{(2)} \leq \dots \leq p_{(m)}$. The test begins by comparing the smallest p -value $p_{(1)}$ to α/m . If this $p_{(1)}$ is less than α/m , the hypothesis $H_{(1)}$ associated with this p -value is rejected. The testing then continues to the next step comparing the next smallest p -value $p_{(2)}$ to $\alpha/(m-1)$. The hypothesis $H_{(2)}$ associated with $p_{(2)}$ is then rejected if $p_{(2)} < \alpha/(m-1)$. This testing continues by comparing the subsequent ordered p -values to the corresponding alpha critical values of $\alpha/(m-2), \dots, \alpha$, as long as the previous hypotheses are rejected. Once a hypothesis is not rejected, the remaining hypotheses with larger ordered p -values are not rejected. The Holm's test is in general more powerful than the Bonferroni test. As an example, consider a clinical trial that produces two-sided p -values of 0.015, 0.024 and 0.045 for the three primary endpoints of the trial. The unweighted Bonferroni test will conclude statistical significance only for the endpoint with p -value of 0.015 because 0.015 is less than $0.05/3$. On the other hand, the Holm's test will conclude statistical significance for all three endpoints.

The weighted version of the Holm's test can be carried out as follows.^[16] Let $w_1, w_2, \dots, w_m$ be the positive weights as defined above and $q_j = p_j/w_j$ for $j = 1, \dots, m$. Then order q_j values in increasing order as $q_{(1)} \leq q_{(2)} \leq \dots \leq q_{(m)}$, and let $w_{(1)}, w_{(2)}, \dots, w_{(m)}$ be the corresponding weights. Further, let $W_{(j)} = \sum_{i=j}^m w_{(i)}$ for $j = 1, \dots, m$, be the total (for $j = 1$) and partial sums (for $j > 1$) of these weights. The test starts by comparing the smallest $q_{(1)}$ to $\alpha/W_{(1)}$. If $q_{(1)}$ is less than $\alpha/W_{(1)}$, the hypothesis associated with this $q_{(1)}$ is then rejected. The testing then continues to the next step comparing the next smallest $q_{(2)}$ to $\alpha/W_{(2)}$ to check if $q_{(2)} < \alpha/W_{(2)}$ for the rejection of the hypothesis associated with $q_{(2)}$. If this hypothesis is rejected, then testing continues to comparing the subsequent ordered q_j values to corresponding alpha critical values of $\alpha/W_{(j)}$ as long as all previous hypotheses were rejected. The weighting scheme increases the power for

those hypotheses with larger weights at the cost of reducing the power for those hypotheses with smaller weights. Note that if the weights are all equal, that is, $w_j = 1/m$ for $j = 1, \dots, m$, then the weighted Holm's test reduces to the unweighted Holm's test.

Hommel and Hochberg Tests

Hommel and Hochberg^[17,18] have proposed step-up tests that can be more powerful than the Holm's test. The Hochberg test has become popular because of its simplicity, and its use is well accepted for independent and for certain types of positively correlated test statistics. However, in general, it does not control FWER in the strong sense^[19] for all dependent hypotheses. For this reason, it is seldom used for the primary objectives of a trial. The Hochberg test with equal weights uses the same p -values and alpha critical values as those used in the Holm's test. However, it is a step-up test, and as such, it starts with the largest p -value, and rejects all hypotheses with smaller p -values when a p -value is less than its alpha critical value. The Hochberg test can also be used with weights.^[20] Consider a trial that produces two-sided p -values of 0.035, 0.040, and 0.045 for the three primary endpoint tests. The unweighted Bonferroni and Holm's tests will not conclude any of these three p -values as statistically significant at the 0.05 level, but the unweighted Hochberg test will conclude all three p -values as statistically significant at this level.

PAAS and Šidák's Test

Moyé^[21] has proposed the prospective alpha allocation scheme (PAAS) for testing multiple hypotheses of a trial. This has slight advantage in power over the Bonferroni test. Its use is well recognized for independent and positively correlated test statistics. However, for other cases it does not guarantee FWER control in the strong sense. Adjusted p -values $q_j = p_j/w_j$ and alpha critical values $\alpha_j = w_j\alpha$ are calculated on assuming independence between test statistics to satisfy the equation

$$(1 - w_1\alpha)(1 - w_2\alpha) \cdots (1 - w_m\alpha) = (1 - \alpha).$$

In the Šidák's procedure,^[22] each individual hypothesis test in a family of m hypotheses is carried out at the alpha critical value of $\alpha^* = 1 - (1 - \alpha)^{1/m}$. This method similar to PAAS is recommended when the comparison tests are either independent or positively correlated. It is conservative in declaring significance similar to Bonferroni and PAAS.

Extensions of Šidák's Test

Šidák's independence adjustment formula $\alpha^* = 1 - (1 - \alpha)^{1/m}$, although conservative for positively correlated test statistics, is very attractive and easy to use. It readily converts

to simultaneous confidence intervals. Therefore, there has been interest in ad hoc modifications of this independence formula that incorporate correlation information for making it less conservative when testing for treatment effects of moderate to highly correlated endpoints of early phase trials or for secondary and safety endpoints of a trial, and for other situations where strict FWER control in the strong sense is not needed. In this regard, one suggestion^[23] was to replace m by $m' = \sqrt{m}$. Surprisingly, this simple algorithm works well for highly correlated tests. Subsequently, Dubey,^[24] based on the ideas of Tukey et al.^[23] and Armitage,^[25] proposed a "multi-correlated endpoint metric," in which the multiplicity adjustment for each of the m response variables depends on how that response variable "on the average" is inter-correlated with the remaining $(m - 1)$ response variables. This multi-correlated endpoint metric approach has been further improved^[26,27] for better FWER control. These improvements easily provide adjusted confidence intervals which are often considered necessary to report for clinical trials.

Fixed and Flexible Fixed-Sequence (Fallback) Methods

In the fixed sequence (FS) method, hypotheses are tested in a pre-specified order at the full alpha level as long as all preceding hypotheses are rejected. Once a testing sequence breaks (that is, a hypothesis is not rejected) subsequent hypotheses cannot be tested. This method is useful for situations when a hypothesis has to be tested first otherwise there is no meaning in testing the second hypothesis. For example, some osteoporosis prevention trials in post-menopausal women test two primary endpoints, which are the incidence of endometrial hyperplasia (EH) and the percent change in lumbar spine bone mineral density (BMD) at one year. Unless the incidence of EH, which is a critical safety endpoint, is ruled at a level x (e.g., $x = 4\%$) by an α -level test with some other clinical safety constraints, such as the point estimate of EH not to exceed 1% in a one year trial, it may not be meaningful to test for efficacy for the BMD endpoint.

A disadvantage of the fixed-sequence testing method is that once a hypothesis in the sequence is not rejected, no efficacy can be claimed for the subsequent hypotheses regardless of their clinical relevance or how small the p -values were, if they were tested. This has been the cause of difficulties in interpreting some clinical trials. An example is the carvedilol trials.^[28,29] In this case, the experimental treatment failed to show a statistically significant result for the planned primary endpoint, namely change in the exercise tolerance which was tested first at the 5% α -level, but the p -value for mortality endpoint was quite small—smaller than the 1% level. From a statistical perspective, as all alpha was spent in testing the exercise endpoint, the mortality endpoint was not considered statistically significant. However, clinicians were not

convinced by this argument, and with some debate and clinical evaluation of the findings, they trumped the result in favor of treatment benefit for the mortality endpoint. The flexible fixed-sequence (FFS) methods, commonly known by the name “fallback” methods,^[30,31] then came about as improvements of the trial design for the purpose of avoiding these types of situations. This method allows testing of subsequent hypotheses in a sequence even if a test in the testing sequence is not rejected.

In the case of testing two null hypotheses H_1 and H_2 , the conventional fallback method tests H_1 at level α_1 , where $\alpha_1 < \alpha$; both α_1 and the total α are pre-specified. If H_1 is rejected, then H_2 is tested at the full significance level of α , otherwise it is tested at the reduced significance level of $\alpha_2 = \alpha - \alpha_1$. The case of testing more than two hypotheses in the fallback method has been straightforward. In addition, extension of this fallback method for parametric models, known as the parametric fallback method, is also available.^[32]

The Adaptive Alpha Allocation Approach (4A) and the Consistency Ensured Methods

The fallback method and its extensions are attractive in saving alpha for testing additional hypotheses. However, they do not go beyond PAAS for increasing the chance of a positive trial in rejecting the second hypothesis H_2 if the trial does not establish treatment efficacy on the first hypothesis H_1 . The adaptive alpha allocation approach (4A) by Li and Mehrotra^[33] is an interesting improvement in this regard. It takes into account the result of testing H_1 for determining the significance level for testing H_2 , consequently leading to some increase in power for testing H_2 . Like the fallback method, the 4A method tests the first hypothesis H_1 at level α_1 , which is at a level somewhat less than the full α . The test procedure tests the second hypothesis H_2 at the significance level α_2 which is determined adaptively by using a non-increasing function of the observed *p*-value associated with H_1 . Interestingly, this α_2 can either exceed or be less than α_1 , even when the first hypothesis H_1 is not rejected at level α_2 . It exceeds α_1 when the *p*-value associated with H_1 is small enough, and it is less than α_1 when the *p*-value for testing H_1 is large enough. Thus, in this method, a weaker result for the first hypothesis requires a much stronger result for the second hypothesis.

For clinical trial applications, the 4A method in hierarchical testing of two primary endpoints—a single primary endpoint and its alternative—takes advantage of the level of evidence of the treatment effect in the first endpoint to determine the significance level for testing for the second endpoint. However, like other methods, it allows for establishing efficacy for the second alternative primary endpoint even if the results for the first endpoint were very weak, or were in the opposite direction (i.e., in the harmful direction). This raises a potential

interpretation issue in study findings when each of the two primary endpoints is allowed to establish efficacy yet their findings are unexpectedly quite inconsistent with each other. Some methods are now available for addressing this case, which require establishing a certain degree of evidence of positive result for the first hypothesis at a minimum before proceeding to test for the second hypothesis.^[34–36] These methods aim to ensure a certain degree of consistency in efficacy findings and are particularly useful in testing for treatment effect in a targeted subgroup of patients when the total population *p*-value—if not statistically significant in favor of the treatment—has to show some consistency of result with the subgroup finding.

Dunnett's Test

This is to date a classical and a frequently used test for many randomized laboratory experiments and even for clinical trials where multiple-treatment means are compared to that of the control; the multiple treatments are often multiple doses of the same treatment.^[5] This is an easy to use method and allows both one-sided and two-sided significance tests and confidence interval calculations. The multi-step versions of the test are also available.^[37] However, these tests are primarily designed for continuous endpoints under certain general linear model assumptions.

Scheffe, Tukey, and Tukey-Kramer Procedures

These procedures give great flexibility for many randomized biological experiments in which variations between experimental units are not of major concern and the experimenter is not able to specify specific comparisons or contrasts in advance. Scheffe's procedure provides a way of looking into all possible linear contrasts of *m* treatment means without worrying about the type I error rate inflation. Similarly, Tukey and Tukey-Kramer procedures provide tests and confidence intervals for all possible pairwise comparisons of the treatment means.^[5,38] However, as the number *m* increases, these methods become quite conservative in declaring significance in comparison to approaches that pre-specify a small number of test contrasts. Note that these tests are designed for continuous endpoints when certain general linear model assumptions hold.

Exact Tests of Contrasts

Given a specific family of test contrasts, software is now available that provides exact tests and simultaneous confidence intervals for many situations using simulation techniques.^[39] This technology assures that a multiple testing procedure (MTP) can be found for a specific application that is neither conservative nor liberal as long as the family of test contrasts is specified in advance.

MULTIPLE HYPOTHESES TESTING PRINCIPLES

Often clinical trials designs lead to complex multiplicity issues for which standard methods may not readily apply. However, there are some useful multiple hypotheses testing principles that can help in developing a suitable statistical testing strategy for solving such a multiplicity problem. Below we introduce some of these principles. Interestingly, some of the well-known multiplicity adjustment methods follow from one or more of these principles. For example, the Hochberg method was derived by applying the closed testing principle to the Simes's global test procedure.^[18] The sequential and parallel gatekeeping methods and their variations follow from the hierarchical testing and closed testing principles.

Union-Intersection (UI) and Intersection-Union (IU) Testing Principles

This is a useful principle for testing multiple hypotheses and for obtaining simultaneous confidence intervals or regions.^[5,40] The potential of this method for multivariate data, correlated endpoints, and specific interest decision rules is still being researched. As before, let H_j (for $j = 1, \dots, m$) represent m component null hypotheses, and let C_j 's be their corresponding rejection regions, and C their union. Then the α -levels, that is, the sizes of C_j 's are so adjusted that the overall size of C is $\leq \alpha$. In this setup, as the overall rejection region is the union of the individual rejection regions of the component null hypotheses, the acceptance region is the intersection of the complement of these individual rejection regions, leading to a UI scenario. The overall null hypothesis having this region of rejection C is often called the intersection null hypothesis and the alternative as the alternative union hypothesis. In the UI scenario, the intersection hypothesis being false implies that at least one of the component null hypotheses is false, and the intersection hypothesis being true implies that all component hypotheses are true.

An alternate situation often arises, for example, when given m multiple primary clinical endpoints, a clinical decision rule may require significant results in all the m endpoints. This situation gives rise to an intersection-union (IU) testing scenario. The overall rejection region is the intersection of the individual rejection regions of the component nulls and the acceptance region is the union of the complement of these individual rejection regions. The null hypothesis for this case is then the union of the component null hypotheses. There is no multiplicity adjustment for IU testing if each test is performed at the same level α (e.g., $\alpha = 0.05$), but it impacts the type II error rate, and consequently, the size of the trial. The maximum type I error rate for IU testing is the same as α if each individual test is performed at level α . Often, clinical decision rule in a clinical trial requires that r out of the m multiple endpoints show effectiveness. This scenario requires combining the

IU and UI strategies in setting up the null and alternative hypotheses.

Global Testing

Global tests are designed to test the global null hypothesis for a given family of null hypotheses. In this hypothesis, one assumes that all null hypotheses are true null hypotheses. A null hypothesis of the type $H_0^{(m)}: \delta_1 = 0, \delta_2 = 0, \dots, \delta_m = 0$ is a global null hypothesis of dimension m , also it is called the intersection hypothesis of dimension m . In this hypothesis, $\delta_j = 0$, for example, could be the parameter indicating the treatment effect of the j th endpoint in testing for m endpoints. A global test follows the union-intersection principle and is generally used to find a combined treatment effect across several endpoints. It can be more powerful than tests for individual endpoints in the presence of such a combined effect. On the other hand, it can be less powerful than the individual endpoint tests if the treatment effect is located in a very few isolated endpoints.

However, once a global test result is found statistically significant, the usual interest is to find out which endpoints or which component hypotheses are specifically responsible for such a treatment effect. One way to achieve this specificity goal is to apply the so-called "closure principle" to the global test method used. This is addressed in the next section. Some examples of global tests are Hotelling's T^2 test, O'Brien's OLS/GLS tests, O'Brien's rank-sum global test, Simes' test, Läuter exact test, and the likelihood ratio-based global tests.^[26,41–43]

Closed Testing Principle

The closed testing principle, proposed by Marcus et al.,^[44] is an important general purpose principle for solving many multiple testing problems that arise in all sorts of pharmaceutical experiments including clinical trials. The principle is fairly simple and basic. Many multiple testing methods, such as Holm's,^[15] Hommel's,^[17] and Hochberg's^[18] tests follow from this principle. The first step in this principle, when given a family of m (null) hypotheses to test, is to construct a closed family of intersection hypotheses. That is, if any two intersection hypotheses belong to this family, then their intersection also belongs to this family. By definition, it also includes the m individual hypotheses and the global null hypothesis. For example, given a family of three endpoint hypotheses H_1, H_2 , and H_3 to test, the family $\{H_1 \cap H_2 \cap H_3, H_1 \cap H_2, H_1 \cap H_3, H_2 \cap H_3, H_1, H_2, H_3\}$ is such a closed family under intersection. The notation $H_1 \cap H_2 \cap H_3$ stands for the intersection hypothesis of dimension 3, where $\delta_1 = 0, \delta_2 = 0$, and $\delta_3 = 0$; $H_1 \cap H_2$ for the intersection hypotheses of dimension 2, where $\delta_1 = 0$ and $\delta_2 = 0$; H_1 for the hypothesis $\delta_1 = 0$; and so on.

The closure principle states that a testing procedure that controls FWER in the strong sense can be constructed by testing each intersection hypothesis (and each individual

hypothesis) in this family using a suitable α -level test that controls FWER at least in the weak sense. Such an α -level test can be an appropriate α -level global test. This procedure rejects a hypothesis of this family if all intersection hypotheses in that family containing that specific hypothesis are rejected. In the example of the three endpoint hypotheses, in order to reject H_1 at level α , each of the four hypotheses $H_1 \cap H_2 \cap H_3$, $H_1 \cap H_2$, $H_1 \cap H_3$, and H_1 must be rejected by a suitable α -level test. Lehman et al.,^[45] for example, applied the closure principle with the OLS and GLS global tests for inferences on individual endpoints.

The closed testing has some interesting features. In order to claim a result for a specific endpoint, it requires that this endpoint must show level α test results by itself and also in association with all other endpoints in the family in all possible combinations. This is a sensible scientific requirement given the possibilities of multiple scenarios of effects and no effects in the multiple endpoints in association with the given endpoint of interest. A closed testing procedure is useful for the case when specific endpoints have modest treatment effects. In this case, individual endpoints may fail to show results, but jointly they may show a result on collecting strengths from each other. This concept is similar to that in meta-analysis of multiple studies, when individual studies may fail to show results but collectively they may have a result. For example, for the three-endpoint case, H_1 and H_2 may not be rejected at level α because of modest treatment effects for each, but $H_1 \cap H_2 \cap H_3$, $H_1 \cap H_2$ may be rejected each at level α establishing a result for α joint effect of endpoints 1 and 2.

There has been some interest in investigating shortcut approaches to performing closed tests. In this regard, it is interesting to note that the close testing principle with the Bonferroni test or the weighted Bonferroni test of intersection hypotheses of different dimensions, leads to the corresponding unweighted and weighted Holm's tests as shortcut methods. In this exercise, the Bonferroni test would reject an intersection hypothesis of dimension k , if the minimum of p -values associated with the individual hypotheses in that intersection is less than α/k .

Partitioning Principle

The partitioning principle is another interesting idea for performing multiple hypotheses tests. However, at present only limited literature is available on this topic.^[46,47] The idea is to first partition the union of hypotheses into disjoint hypotheses. Then test each disjoint hypothesis at the same level α . This, similar to close testing, does not compromise the FWER control at level α . Note that the partitioning principle does not depend on the closed family of intersection hypotheses. An attractive feature of this principle is that it can also provide simultaneous confidence intervals.

As an example, consider a clinical trial in which, for a given clinical endpoint X , two doses D_1 and D_2 are compared to a control D_0 . Let θ_0 , θ_1 , and θ_2 be expected parameter values of X for these dosages. Consider the following parameter space partitions: $A = \{\theta_1 \leq \theta_0, \theta_2 \leq \theta_0\}$, $B = \{\theta_1 \leq \theta_0, \theta_2 > \theta_0\}$, $C = \{\theta_1 > \theta_0, \theta_2 \leq \theta_0\}$, and $D = \{\theta_1 > \theta_0, \theta_2 > \theta_0\}$. Note that A , B , C , and D are disjoint and add up to the total joint parameter space of θ_1 and θ_2 . One can then test the following hypotheses in sequential steps as shown.

- Step 1: Test the null H_{01} : $\omega \in A$ versus H_{a1} : $\omega \in A^c$ (complement of A). If H_{01} is rejected then conclude that at least $\theta_1 > \theta_0$ or $\theta_2 > \theta_0$, and go to Step 2 else stop.
- Step 2: H_{02} : $\omega \in B$ versus H_{a2} : $\omega \in (A \cup B)^c = \{\theta_1 > \theta_0\}$. If H_{02} is rejected then conclude that $\theta_1 > \theta_0$, else stop.
- Step 3: Test the null H_{03} : $\omega \in C$ versus H_{a3} : $\omega \in (A \cup B \cup C)^c = \{\theta_1 > \theta_0, \theta_2 > \theta_0\}$. If H_{03} is rejected then conclude that in addition to $\theta_1 > \theta_0$, also $\theta_2 > \theta_0$.

Hierarchical Testing Principle/Framework

Because various objectives of a trial differ in importance with respect to regulatory and scientific utility, a useful and efficient statistical framework for addressing multiplicity problems of trials is to rank-order the objectives of the trial into primary and secondary objectives. In addition, if there are several primary objectives, then they can be rank-ordered as well provided that this is clinically meaningful. In the statistical terminology, this rank-ordering of the objectives of a trial is known as hierarchical ordering of families of hypotheses of a trial. In this framework, one addresses multiplicity issues for the primary objectives first independent of the other objectives of the trial as if the other objectives did not exist. This framework has an advantage in that it allows recycling of used alpha, either in full or part (depending on the testing scheme), from a family of hypotheses to the next family for those hypotheses of the previous family which are statistically significant.^[48–53]

Note that the primary objective of the trial traditionally determines whether the trial is positively successful or not with respect to planned primary endpoints. If a trial is positive, it can characterize clinically meaningful benefits of the study treatment. Primary endpoints for this purpose are usually important clinical endpoints. These are few in number, usually 1–4, and trials are normally sufficiently powered for these endpoints for detecting meaningful treatment differences. After primary objectives of the trial are meaningfully met, and the trial is found to be a positive trial, then one can go ahead and address multiplicity for secondary objectives according to a prospectively planned test strategy. However, solving multiplicity problems for the primary and secondary objective requires formulating the problem and its solutions at the design stage.

Gatekeeping Testing Strategies

Gatekeeping testing strategies are useful in solving many clinical trial multiplicity problems that can be framed in terms of testing of hierarchical families of multiple hypotheses. The families of hypotheses are examined sequentially with each family serving as a gatekeeper for the subsequent families. Two types of gatekeeping testing strategies are popular: *parallel* and *serial*. In the serial strategy, one tests hypotheses within each family (gate) using a method that controls the familywise error rate for each gate and proceeds to the next gate when all of the hypotheses in the current gate are rejected.^[52] On the other hand, the parallel gatekeeping strategy requires only the rejection of at least one hypothesis in each gate.^[53]

As an illustration, consider a trial in which the primary objective is to show superiority of a test treatment to placebo for endpoints A and B, and then to test for superiority for the two endpoints C and D after this primary objective is met. This problem fits into the gatekeeping testing framework of the two families of hypotheses $F_1 = \{H_A, H_B\}$ and $F_2 = \{H_C, H_D\}$ as these two families are hierarchically ordered. There can be twotypes of clinical decision criteria for meeting the primary objective. In one, both A and B need to show statistically significant treatment benefits, because both endpoints A and B are needed to characterize a meaningful treatment benefit. In the other, a statistically significant treatment benefit in either A or B is sufficient to characterize treatment benefit. In the first type the F_1 gate in the gatekeeping method is of serial and in the second type it is of parallel nature.

Gatekeeping testing strategies are based on the closed testing principle that requires tracking $2^n - 1$ intersection hypotheses, n being the total number hypotheses across all families of hypotheses, as such, algorithms^[53] become messy for many applications. However, these methods guarantee FWER control at level α in the strong sense as long as the intersection hypotheses tests in the closed testing algorithms have the FWER control at level α . If the parallel gatekeeping procedure uses the weighted Bonferroni test method for testing intersection hypotheses in its closed testing algorithm, then it is called the Bonferroni parallel gatekeeping procedure. This procedure is of special interest as it allows a simple shortcut method for clinical trial applications.

This shortcut method is built around the concept of *rejection gain factor*. A formula for calculating this rejection gain factor, and some examples of applications of this shortcut method, can be found in Dmitrienko-Tamhane et al. articles.^[50,51] This Bonferroni based shortcut method basically allows recycling of alpha by this gain factor formula from one family to the next for those hypotheses that are rejected in the previous family. Consider, for example, $F_1 = \{H_A, H_B\}$, and say that H_A was tested at level $\alpha_1 = w_1\alpha = 0.035$ and H_B at level $\alpha_2 = w_2\alpha = 0.01$, with $w_1 + w_2 = 0.9 < 1$, and in this testing, H_A was rejected but H_B was

not rejected. Then the alpha of 0.035, associated with H_A , can be recycled (i.e., passed) from F_1 to F_2 giving a total alpha of $0.035 + 0.005 = 0.04$ for testing H_C and H_D in F_2 by the Holm's test.

MULTIPLICITY CONSIDERATIONS FOR SOME CLINICAL TRIALS

Clinical Decision Rules

A useful road map for identifying and addressing multiplicity for confirmatory control clinical trials is to outline at the design stage of the trial the “win” scenarios, which are sometimes referred to as clinical decision rules. This win criteria would specify how a positive clinical decision regarding the effectiveness of the study treatment is going to be reached based on the results of one or more primary endpoints or based on one or more dose-control treatment comparisons. These win scenarios are basically a set of prospectively defined decision rules in terms of statistical results of the primary endpoints and primary treatment comparisons that determines whether the trial is successful or not. If the trial is successful in this way, then one is able to characterize meaningful benefits of the study treatment. Such criteria represent a clinically acceptable way of assessing benefits of a treatment for the disease and patient population under consideration. Statistically, such win criteria for a clinical trial refer to alternative hypotheses and the corresponding complements to their null hypotheses situations. In the following discussion, we list some examples of such win criteria or clinical decision rules in terms of primary endpoint(s) for trials that compare a treatment to a control.

1. Given a single specified primary endpoint that can characterize treatment benefit, the treatment needs to be superior to the control for this endpoint.
2. Given several specified primary endpoints that can independently characterize treatment benefit, the treatment needs to be superior to the control for at least one of them.
3. Given m ($m \geq 2$) specified primary endpoints, the treatment needs to be superior to the control for all of them for a meaningful treatment benefit.
4. Given three specified primary endpoints E_1 , E_2 , and E_3 , the treatment needs to be superior to the control either for E_1 or for both E_2 and E_3 .
5. Given three specified primary endpoints E_1 , E_2 , and E_3 , the treatment needs to be superior to the control either for (E_1 and E_2) or for (E_1 and E_3).
6. Given two specified primary endpoints, the treatment needs to be superior to the control for one and at least marginally superior to the control for the other.
7. Given two specified primary endpoints, the treatment needs to be superior to the control for one and at least non-inferior to the control for the other.

8. Given several endpoints that are in a hierarchy that specifies the order in which they are to be evaluated, and significance of all preceding endpoints is required in order to proceed to the next one.
9. Given m specified primary endpoints, at least k of them needs to be statistically significant in favor of the treatment and the remaining $(m-k)$ endpoints show at least a trend in the right direction.

Note that decision rules for wining in examples 1, 3, 7, and 8 do not require any multiplicity adjustment. Each test can be carried out at the same level α without any adjustment. The null hypothesis structure for some of the above rules may not be straightforward like the simple intersection or union null hypothesis of m individual hypotheses; it may involve a mixture of these. Solutions to these problems can found on applying some of the principles and concepts introduced in the section “Multiple Hypotheses Testing Principles”.

Primary and Secondary Endpoint Concepts

Primary endpoints in clinical trials play an important role in characterizing treatment benefits and in achieving the main objectives of the trial. Key design features of the trial generally depend on the primary endpoint specifications, such as trial size, data monitoring, and analysis strategies. Secondary endpoints also play an important role in providing additional information, for example, for interpreting results of the primary endpoints, for expanding or providing additional characterization of treatment effects, and also for generating new hypotheses for future trials.^[54–58] Secondary endpoints by themselves are generally considered not sufficient for characterizing treatment benefits. However, if a secondary endpoint is an endpoint like mortality or irreversible morbidity, it could reach the status of a primary endpoint.

Composite Endpoint Issues

Often trials, particularly cardiovascular trials, combine events from component endpoints to construct a composite in order to increase the number of events for such an endpoint. An example is the first occurrence of death, myocardial infarction (MI), or recurrent angina for a cardiovascular trial. Such a construct gives more power to the statistical test for treatment difference if each component included in the composite has some sensitivity for detecting treatment difference. However, if a component endpoint included in the composite has no such sensitivity, it may instead hurt the cause by adding more noise to the composite.

A composite-endpoint-based statistical test provides an overall test for the component endpoints in the composite. Testing of the individual components in the composite requires adjustment for multiplicity when claiming treatment efficacy for specific components. However, difficulties arise in an analysis of a specific individual component

of the composite, as the events of the other components become censored observations. In addition, clinical interpretation of the composite is often difficult when its softer components drive the result or all its components do not trend positively.

There are some key considerations and issues requiring attention when using a composite endpoint as a primary endpoint.^[59–62] For example, the components of a composite endpoint must be clinically relevant, consistent or coherent with each other, and interpretable for the disease and the intervention under study. One should prospectively define the composite endpoint itself and all its components along with their ascertainment methods. Component endpoints are to add to the total treatment effect with induced treatment effects in a similar direction. Endpoint ascertainment methods are to capture accurately both the occurrence and non-occurrence of the component events. The results of the component endpoints are to be fully disclosed and displayed along with the results of their composite to allow a meaningful interpretation of the composite endpoint result.

A composite endpoint is usually not recommended as a primary endpoint when its components can be of widely differing importance to patients and can occur with differing frequency, and their magnitude of effects can vary markedly. Such a situation can complicate interpreting the result of a composite.

Approaches for Reducing the Burden of Multiplicity

Clinical trials generally test many hypotheses. This can easily overload a trial with excessive multiplicity burden. Therefore, one of the considerations in designing a trial is to try to gain efficiency by reducing the burden of multiplicity as much as possible. In this regard, several approaches may be taken. A popular approach is to order the families of hypotheses hierarchically as well as, where possible, the hypotheses within each family. Families of null hypotheses are said to be hierarchically ordered or ranked if earlier families serve as gatekeepers in the sense that one tests hypotheses in a given family if the preceding gatekeepers have been successfully passed. The two commonly used hierarchical families of endpoints in a clinical trial are the family of primary endpoints and the family of secondary endpoints. These two families are hierarchically ordered with the property that rejections or non-rejections of null hypotheses of primary endpoints do not depend on the results of the secondary endpoints. This allows the use of gatekeeping testing strategies that can considerably reduce the multiplicity burden in controlling the familywise error rate.

The use of dependence information between the test statistics, if available, can also help in reducing the extent of multiplicity. Another approach in this regard is to combine several endpoints to a single or to a few composite endpoints, if certain conditions are met and if such composite endpoints are clinically acceptable.

Dose-Response and Dose-Control Comparison Trials

These trials are generally carried out for early phase trials in contrast to confirmatory trials. Given the dose-response data on an endpoint at m doses of a test treatment, the early phase trials fit a set of suitable parametric dose-response models, such as E -max and logistic models and their variants. A working model, which is the best candidate for describing the dose response relationship, is then selected from these fitted models on performing statistical tests of model-contrasts. This working model is then used for proof of activity of the test treatment in the dose range of the trial and for deciding which few doses should be selected for the confirmatory trial. In this approach, the need for multiplicity adjustments arises for addressing uncertainty in model selection. Bretz et al.^[63] have provided a method for handling this multiplicity issue. Some early trials also use multiple comparisons based approach which treats dose as a qualitative factor with a very few assumptions, if any, about the underlying dose response model. This approach is often used for identifying minimum effective dose (MED) dose.^[64]

Confirmatory trials with multiple doses, however, are dose-control comparison trials with a basic design that includes m doses ($d_1, \dots, d_m$) of the test treatment, placebo (d_0), and at least one dose of a relevant active control. The value of m is generally small and the goal of such a trial is to prove overall efficacy of the test treatment and for its targeted doses, and in addition, if a dose is effective, to assess its standing in comparison to the active control of the trial. Bauer et al.^[65] have investigated this design in detail and have proposed various inferential strategies for dealing with questions of interest and multiplicity issues. There are variations of this basic design: some assume order restriction among doses and some do not; some exclude placebo for ethical reasons; some exclude the active control arm; and some perform superiority as well as non-inferiority tests. Some trials make dose-comparisons on multiple primary and secondary endpoints with logical restrictions, such as a dose-comparison for a secondary endpoint cannot be made unless such a comparison for the primary endpoint is statistically significant. These dose-control comparison designs raise multiplicity problems at advance levels. These advance multiplicity problems are often solved by the tree-structured gatekeeping procedures,^[66] which combine the serial and parallel gatekeeping features with logical restrictions.

Three-Arm “Gold Standard” Trials

Active control trials when conducted with three treatment arms, a placebo (P), an approved active control (S) and the test treatment (T) are often referred to as three-arm “gold standard” trials. These trials are common for non-serious diseases when treating patients in the trial with placebo is

not unethical. The objective of such a trial is normally two-fold; that is, the trial has assay sensitivity and the new treatment retains efficacy in comparison to the control by more than a prespecified percentage λ_0 . Showing assay sensitivity requires testing $H_1: \mu_S - \mu_P \leq 0$ versus $H_{a1}: \mu_S - \mu_P > 0$ and confirming that the size of the effect $\mu_S - \mu_P$ is in line with the previous historical experience in the patient population studied in this trial. The parameters μ_P , μ_S , and μ_T stand for the expected mean responses for the three treatment arms; a greater treatment mean implies a greater treatment benefit. Showing at least λ_0 percent retention requires testing $H_2: \lambda \leq \lambda_0$ versus $H_{a2}: \lambda > \lambda_0$, where $\lambda = (\mu_T - \mu_P)/(\mu_S - \mu_P)$.

A rigorous statistical solution to the problem that would address all aspects of this problem is a topic of current research. However, some statistical literature is available that address multiple comparison issues of such trials.^[67–69] This design would normally require allocating more patients to the active arms than to placebo, depending on the size of the treatment effects, specification of λ_0 , and variability of the measurements.

Drug Combination Trials

Some diseases require treatment with a combination drug. A two-active combination drug trial has four treatment arms: a combination arm, two component arms, and a placebo arm. The trial aims to show the contribution to efficacy of each component and that the combination is superior to each component. Sometimes these trials are three-arm trials without placebo, provided that each component is an approved product for efficacy and safety. Each comparison test is an α -level test and there is no type I error rate inflation issue. However, the type II error is an issue. It is often harder to show the superiority of the combination over the most effective component. Therefore, the trial may need design improvements to reduce variability.

The win criterion for efficacy for a drug combination trial can become complicated if two or more primary endpoints or two or more components are required in a trial to show the benefit of the combination over its approved components. For example, for the case of two endpoints, the win criterion for efficacy of the combination may be to show superiority for one endpoint and at least non-inferiority for the other endpoint when comparing the combination to each component.^[70] Sometimes multi-dose factorial designs are employed for the assessment of combination drugs for serving dual purpose, to provide confirmatory evidence that the combination is more effective than either component and to identify an effective and safe dose combination or a range of useful dose combinations.^[71]

Subgroup Analysis

Subgroup analyses are widespread in clinical trials, especially for large confirmatory trials. Sometimes the purpose of this analysis is exploratory to find out whether the

efficacy results are consistent across clinically relevant subgroups, such as race, gender, age, and region. Sometimes it is used to explore the possibility of large treatment differences in certain subgroups—for example, patients whose disease is caught early versus patients whose disease has progressed to a certain stage. However, subgroup analyses generally pose analytical challenges and difficult inferential issues including multiplicity and lack of power issues. Interpretation of subgroup analysis results can be problematic unless it is pre-specified at the design stage based on certain background factors that are clinically relevant. It is well understood in the clinical trial literature that subgroup analyses are an important part of the analysis of comparative trials, but their results are frequently exaggerated and often misinterpreted leading to misguided research and suboptimal patient care.^[72–74]

Among the factors which reduce the reliability of subgroup findings is that often subgroup analyses are data driven and unplanned. The biological plausibility of positive findings is argued after the data has been analyzed and results seen. These analyses may have been based on improper subgroups, characterized by a variable measured after randomization and potentially affected by treatment and study procedures. Such unplanned subgroup analyses usually produce false positive results because of bias and multiplicity issues, and also produce false negative results because of lack of power. Therefore, their *p*-values in general cannot be validly interpreted.

On the other hand, interpretation of subgroup findings is enhanced if the clinical trial had planned at the design stage to evaluate treatment effects in a targeted subgroup of patients selected by means of a classifier (such as a biomarker classifier) that is able to select potential responders to the treatment. A subgroup analysis, whether planned or unplanned, can experience a significant loss of power in detecting a treatment effect. However, this loss may not occur for such a targeted subgroup if its treatment effect size happens to be sufficiently greater than that for the total patient population of the trial. Several authors have addressed this type of design and their analyses covering both the multiplicity and power issues of treatment comparisons.^[35,75,76] These designs can potentially improve the chance of trial success.

CONCLUDING REMARKS

In this article, we have clarified the role of *p*-values in hypothesis testing and how it provides evidence in favor of a scientific claim in the area of controlled clinical trials. A small *p*-value is an indicator that the data at hand are in conflict with the null hypothesis, and in doing so, it provides evidence in favor of the alternative hypothesis; the smaller this *p*-value the greater this evidence. However, many undesirable factors that could occur in a clinical trial, including poor design and conduct of the trial, could create

bias and make a *p*-value small without having anything to do with the treatment effect. Therefore, clinical trial results must be carefully evaluated to rule out such bias before concluding a treatment benefit.

We have also tried to clarify the difference between statistical evidence and substantial evidence concepts used in regulatory decision making. Substantial evidence for the benefit of a new drug or treatment generally requires statistically conclusive results from at least two adequate and well-controlled trials. In special cases, depending on the seriousness of the disease and ethical and clinical considerations, a single trial result with a sufficiently small *p*-value may provide this evidence. Goodman^[13] shows that if a trial result has an associated *p*-value of 0.05, then the probability of replicating such a result in a second study at the 0.05 significance level is only 50%. It is only when the *p*-value is 0.001 that this replication probability increases to 90%. Other investigators of *p*-values also emphasize that *p*-values in general overestimate the evidence against the null hypothesis. Therefore, we support the idea of a *p*-value less than 0.001 for a result that could qualify substantial evidence status for a treatment benefit claim derived from a single trial, provided such a result after adjusting for multiplicity satisfies within-trial consistency and is clinically meaningful.

Multiplicity is common in clinical trials and requires special attention. Multiplicity inflates the type I error rate, which is the probability of concluding that the treatment is effective when in reality it is not. We have clarified some general concepts relevant to controlling the type I error rate in the presence of multiplicity. In addition, we have explained some basic principles behind some standard procedures, including those of union-intersection and intersection-union methods, closure, fixed-sequence, fallback, partitioning, and gatekeeping testing. We have also elucidated when to use a single-step and when to use a multi-step procedure. A single-step procedure that controls FWER strongly has more clinical utility—in addition to controlling the type I error probability for specific contrasts, it also easily provides their adequate interval estimates. Thus, such a method is useful when, in addition to testing of multiple hypotheses, estimation of treatment effect contrasts are also important. On the other hand, a multi-step procedure usually preserves the power of the test more efficiently.

In dealing with multiple-endpoint issues in clinical trials, it is important to define a family of null hypotheses of main interest considering claims to be made for the treatment effect. Such a family should be tightly chosen based on clinical and statistical considerations, such as desired sensitivity and relevancy of the endpoints with regard to the disease and treatment to be studied in the trial. A closed testing procedure is usually recommended for such a family, as it provides a better inferential picture across multiple endpoints at the global and marginal hypothesis levels. If two main families of null hypotheses are defined, one family for the primary endpoints and the other for

the secondary endpoints, there are ways to approach this problem, which we have addressed in this article.

Often a composite endpoint is constructed out of the multiple individual endpoints. A test for the composite endpoint is a test for an overall effect of the multiple endpoints in the composite. Testing of individual components in the composite requires adjustment for multiplicity, unless these analyses are intended only for the interpretation purposes and not for making new or additional claims of treatment benefits. In general, the use of a composite endpoint as a primary endpoint is not recommended when its components are likely to be of widely differing importance and can occur with differing frequency, and their magnitude of effects can markedly differ. Such a situation can complicate interpreting the result of a composite.

In conclusion, because the subject matter of multiplicity in clinical trials is truly vast and because of space considerations, this article has only briefly addressed relevant issues, and its scope has been limited to basic concepts and practices for addressing multiplicity issues in clinical trials. Some important multiplicity topics, such as interim analyses and adaptive designs, have been omitted.

Correlated Probit Model

Ralitza V. Gueorguieva

Department of Epidemiology and Public Health, Yale University, New Haven, Connecticut, U.S.A.

Abstract

The goals of this entry are to familiarize the reader with correlated probit models and to provide enough information and relevant references so that these models can be successfully applied using available statistical software.

INTRODUCTION

Probit models are commonly used to describe the relation between one or more independent variables and a quantal response (e.g., alive or dead; mild, moderate, or severe degree of illness). They are often motivated from the idea of a latent continuous variable underlying the quantal response and the existence of thresholds, such that if the unobserved continuous variable is below a certain threshold then the observed quantal variable is in a certain response category. For example, if toxicity is below the critical threshold the subject is alive, otherwise the subject is dead. However, the threshold concept and the existence of an underlying continuous variable are not necessary for model interpretability. The usual probit model is used when the sample consists of n independent cases with a single quantal outcome variable, while multivariate probit models are extending the usual probit models to cases of several quantal outcome variables observed on the same individual. In contrast to probit models for independent data, correlated probit models are useful in analyzing one or more quantal response variables when these variables are repeatedly measured within clusters or over time. For example, it may be of interest to model the probability of the presence of a particular illness or symptom in the members of the same family or on the same individual over the course of follow-up in a longitudinal study. As measurements on individuals within the same family or repeated measurements on the same individual are likely to be more highly correlated than measurements on unrelated individuals, special statistical methods are necessary to account for this correlation.

The goals of this entry are to familiarize the reader with correlated probit models and to provide enough information and relevant references so that these models can be successfully applied using available statistical software. To achieve this goal we first introduce the probit, multivariate probit, and correlated probit models, followed by

a discussion on model interpretation, identifiability, and model fitting. An illustrative example of a correlated probit model with both multiple response variables and clustering is provided, followed by a brief overview of available statistical software packages that can be used for model fitting.

HISTORICAL OVERVIEW

Probit Model for Uncorrelated Data

In many applications an observed binary variable y can be assumed to result from a dichotomization of an unobserved (latent) continuous variable y^* ranging from minus infinity to plus infinity. Larger values of y^* are observed as $y = 1$ while smaller values of y^* are observed as $y = 0$. Motivation for this representation often comes from studies of dose–response relationships where, for example, the response of interest is whether an individual receiving a certain dose of a toxic chemical dies.^[1,2] The latent variable y^* is assumed to be linearly related to the observed covariates through the model

$$y_i^* = x_i^T \beta + \varepsilon_i, \quad \varepsilon_i \sim \text{i.i.d. } N(0, \sigma^2) \quad (1)$$

where x_i is a vector of covariates and β is a parameter vector of fixed effects. The observed binary variable is linked to the latent continuous variable by

$$y_i = I\{y_i^* \geq \tau\} \quad (2)$$

where τ represents a threshold.

Then

$$\begin{aligned} P(y_i = 0) &= P(y_i^* < \tau) = P(x_i^T \beta + \varepsilon_i < \tau) \\ &= \Phi\left(\frac{\tau - x_i^T \beta}{\sigma}\right) \end{aligned}$$

$$P(y_i = 1) = P(y_i^* \geq \tau) = P(x_i^T \beta + \varepsilon_i \geq \tau) \\ = \Phi\left(\frac{x_i^T \beta - \tau}{\sigma}\right)$$

where Φ is the cumulative distribution function of a standard normal random variable.

Without loss of generality the threshold τ can be set equal to zero because it can be absorbed in the intercept of the linear predictor ($\beta_0^* = \beta_0 - \tau$). The error variance σ^2 is not estimable from the data because y_i^* is not observed, rather it is only known whether y_i^* is positive or negative. Usually σ^2 is taken to equal 1. Bliss^[3] is credited with the development of the method of probit analysis and the study by Finney^[1] is a useful reference of early work.

Like dichotomous data, ordinal data are also often assumed to arise from an underlying latent continuous variable. Let y_i^* be related to covariates as described in Eq. (1) and let

$$y_i = r \quad \text{if } \tau_{r-1} \leq y_i^* < \tau_r \\ \text{for } r = 1, 2, \dots, R, \tau_0 = -\infty, \\ \tau_R = +\infty, \tau_1 < \tau_2 < \dots < \tau_{R-1} \quad (3)$$

Then

$$P(y_i = r) = P(\tau_{r-1} \leq y_i^* < \tau_r) \\ = \Phi\left(\frac{\tau_r - x_i^T \beta}{\sigma}\right) - \Phi\left(\frac{\tau_{r-1} - x_i^T \beta}{\sigma}\right)$$

This ordered probit model was first suggested by Aitchison and Silvey^[4] who considered only a single independent variable. McKelvey and Zavoina^[5] later extended Aitchison and Silvey's work to the case of multiple independent variables. For identifiability reasons the variance σ^2 is set equal to 1, and either the intercept is set equal to zero, or the thresholds are reparametrized as follows: $\tau_1 = 0, \tau_2^* = \tau_2 - \tau_1, \dots, \tau_{R-1}^* = \tau_{R-1} - \tau_{R-2}$.

Probit models have no significant advantage over logit models for univariate data, but in multivariate data, the probit formulation allows to fully exploit the correlation structure of the data. By taking into account the information on covariates, multivariate probit modeling can be regarded as extension of tetrachoric and polychoric correlation.

Multivariate Probit Model for Multiple Variables or Correlated Data on the Same Variable

Extensions of the above methods to include multiple response variables or clustered data have been considered in the literature. Ashford and Sowden^[2] introduced a multivariate probit model based on an underlying multivariate normal distribution. This model is appropriate when either multiple response variables are measured on the same

individual or when there are repeated measures on the same variable within individual. In the bivariate case there are two correlated underlying latent variables such that

$$\begin{pmatrix} y_{i1}^* \\ y_{i2}^* \end{pmatrix} \sim N \left[\begin{pmatrix} x_{i1}^T \beta \\ x_{i2}^T \beta \end{pmatrix}, \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix} \right], \quad (4) \\ y_{i1} = I(y_{i1}^* \geq 0) \text{ and } y_{i2} = I(y_{i2}^* \geq 0)$$

The joint probabilities for the two binary variables can be obtained based on the univariate normal cumulative distribution function Φ and on the bivariate normal cumulative distribution function $\Phi^{(2)}$

$$P(y_{i1} = 0, y_{i2} = 0) = P(y_{i1}^* < 0, y_{i2}^* < 0) \\ = \Phi^{(2)}(-x_{i1}^T \beta, -x_{i2}^T \beta)$$

$$P(y_{i1} = 0, y_{i2} = 1) = P(y_{i1}^* < 0, y_{i2}^* \geq 0) \\ = P(y_{i1}^* < 0) - P(y_{i1}^* < 0, y_{i2}^* < 0) \\ = \Phi(-x_{i1}^T \beta) - \Phi^{(2)}(-x_{i1}^T \beta, -x_{i2}^T \beta)$$

and the remaining joint probabilities are similarly determined. The marginal probabilities for each variable are

$$P(y_{i1} = 0) = \Phi(-x_{i1}^T \beta), \quad P(y_{i1} = 1) = \Phi(x_{i1}^T \beta), \\ P(y_{i2} = 0) = \Phi(-x_{i2}^T \beta), \quad P(y_{i2} = 1) = \Phi(x_{i2}^T \beta)$$

and hence do not depend on the error correlation of the variables.

Ashford and Sowden's generalization provides a full information maximum likelihood solution for the bivariate case but is computationally intractable for more than two response variables.^[6] Special algorithms have been developed for certain simple types of correlation structures. For example, Ochi and Prentice^[7] introduced a correlated generalization of the multivariate probit model of Ashford and Sowden to fit regression models to exchangeable binary data, i.e., binary data where the correlations between any two binary responses within a cluster are the same. Such situations may occur when repeated measures are taken on subjects within clusters (e.g., students within schools) and there is no particular ordering of subjects within clusters.

In contrast, or in addition to, assuming underlying multivariate normal distribution, many authors have used random effects or a smaller number of latent variables to impose correlation between quantal variables. Random effects models assume that the correlation among repeated measures arises because there is natural heterogeneity across individuals and that this heterogeneity can be represented as a probability distribution. Because of such heterogeneity, observations within subject are likely

to be more highly correlated than observations on different (unrelated) subjects. We now define a general random effects model for binary data, which is often referred to as a correlated probit model.

Correlated Probit Model for Multiple Variables or for Correlated Data on the Same Variable

Herein we assume that repeated observations occur within subject, although we could consider repeated measures within other clustering variables (e.g., school, family) rather than subject. Let y_{ij}^* be the latent response variable for the j th occasion ($j = 1, \dots, n_i$) of the i th subject ($i = 1, \dots, n$), let x_{ij} and z_{ij} be covariate vectors for the j th occasion of the i th subject, and let b_i be a random effects vector for the i th subject. Then the correlated probit model is defined as follows

$$\begin{aligned} y_{ij}^* &= x_{ij}^T \beta + z_{ij}^T b_i + \varepsilon_{ij}, \quad b_i \sim \text{i.i.d. } N(0, \Sigma_b), \\ \varepsilon_{ij} &\sim \text{i.i.d. } N(0, \sigma_\varepsilon^2) \end{aligned} \quad (5)$$

where the random effects and errors are independent. The observed binary response for each occasion within subject is $y_{ij} = I(y_{ij}^* \geq 0)$.

For this model, correlation between repeated observations on the same subject (or within the same cluster) is imposed via the random effects. Thus this model is a special case of the generalized linear mixed model with probit link for the binary response.^[8] However, it is also possible to assume that the errors within individual are correlated as in the multivariate probit model.^[4] When there is a single random intercept and the errors are not correlated, or when there are no random effects and the errors are equicorrelated, this model reduces to Ochi and Prentice's model with an equicorrelated variance–covariance structure. The correlated probit model is very flexible in modeling covariate effects and in accounting for the correlation structure of various types of data; however, there are models more appropriate for data with factor-analytic structure as described by Muthén^[9] and by Bock and Gibbons^[10] or for multilevel data as described by Hedeker and Gibbons,^[11] and by Gibbons and Hedeker.^[12] Also, the assumption of normality of the random effects can be relaxed,^[13] and the variance–covariance parameters can be assumed to depend on covariates.^[14]

Ordinal data is regarded as a generalization of binary data but often poses special challenges for analysis. Random effects regression models for ordinal regression have been considered a number of authors.^[11,15,16] The correlated probit model in Eq. (5) can be generalized to ordinal data by assuming that the observed data are related to the latent continuous variables by Eq. (3).

Correlated data can result from observations on different outcome variables within individual and/or from repeated observations on the same outcome variable

within individual. In the first case it may be more sensible to impose correlation on the error terms, while in the latter case it may make more sense to assume common subject-level random effects with or without correlated errors. Temporal or spatial data can be modeled by assuming a special structure on the errors, while clustering is usually more appropriately modeled by random effects. Some situations can be equivalently modeled by random effects or by random errors. Arguably the most complex scenarios arise when there are both multiple variables (possibly mixtures of binary, ordinal, and continuous) and repeated measures over time. These scenarios require imposing correlation at both the random effects level and at the error level and include all other situations as special cases. It is these latter scenarios that will be the focus of our discussion herein.

Because of complexity and computational difficulties with models for repeated measures on multiple binary, ordinal, and continuous outcomes, it is only in recent years that methods and software have been developed to deal with such data. Catalano and Ryan^[17] and Fitzmaurice and Laird^[18] considered models for clustered bivariate binary and continuous outcomes, and fitted a marginal model for one of the outcomes followed by a conditional model for the other. Gueorguieva and Agresti^[19] extended Chan and Kuk's^[20] probit-normal model for binary data to mixtures of binary and continuous responses and performed joint maximum likelihood estimation of the outcomes via a stochastic expectation maximization (EM) algorithm. Regan and Catalano^[14] considered a generalization of Ochi and Prentice's method for equicorrelated binary and continuous data, while Catalano^[21] and Regan and Catalano^[22] used the generalized estimating equations (GEE) approach to fit a model to a bivariate response consisting of an ordinal and a continuous variable. Geys et al.^[23] considered joint marginal mean models for developmental toxicity studies. Dunson, Chen, and Harry^[24] pioneered a Bayesian approach for jointly modeling cluster size and repeatedly measured binary and continuous outcomes, while Gueorguieva^[25] demonstrated how to perform maximum likelihood estimation on an equivalent model. Herein, we focus on the latter approach that allows for maximum likelihood estimation using existing software.

CORRELATED PROBIT MODEL FOR REPEATEDLY MEASURED COMBINATIONS OF BINARY, ORDINAL, AND CONTINUOUS RESPONSE VARIABLES

We now describe a correlated probit model that encompasses a large number of the models mentioned above as special cases. Let y_{ijv} be the v th response variable ($v = 1, \dots, V$) on occasion j ($j = 1, \dots, n_i$) for individual i ($i = 1, \dots, n$), where y_{ijv} is continuous, binary, or ordinal. Assume an underlying latent variable y_{ijv}^* for each ordinal or binary

response y_{ijv} and that the observed and the latent responses are related as in Eqs. (2) and (3) with, in general, different thresholds for each ordinal variable. The correlated probit model becomes

$$\begin{aligned} y_{ijv}^* &= x_{ijv}^T \beta + z_{ijv}^T b_i + \varepsilon_{ijv}, \\ b_i &\sim \text{i.i.d. } N(0, \Sigma_b), \\ \varepsilon_i &= (\varepsilon_{ij1}, \varepsilon_{ij2}, \dots, \varepsilon_{ijv})^T \sim \text{i.i.d. } N(0, \Sigma_\varepsilon) \end{aligned} \quad (6)$$

where there are, in general, different covariate vectors for each variable. Note that the parameters and the random effects can be shared or separate for different variables. Identifiability constraints can be imposed by setting all diagonal elements of Σ_ε corresponding to ordinal and binary responses equal to 1, setting all intercepts in the linear predictors for ordinal responses equal to 0, and setting the binary thresholds equal to 0.

RELATIONSHIP TO OTHER MODELS

Model (6) contains the models in Eqs. (1), (4), and (5) as special cases. It is also a generalization of the correlated probit model of Gueorguieva and Agresti^[19] to include ordinal responses, of the model of Catalano^[21] to include binary and continuous response and of the two-level formulation of Grilli and Rampichini's^[26] multilevel correlated probit model to include binary and continuous responses.

One can rewrite model (5) as a three-level correlated probit model by introducing occasion within subject-level random effects η_{ij} and assuming independence of the response variables conditional on subject- and occasion-level random effects. That is, the errors and the occasion-level random effects are related by the equation

$$\varepsilon_{ijv} = \gamma_v^T \eta_{ij} + e_{ijv}$$

and additional identifiability constraints on γ_v are imposed. The model formulation then becomes

$$y_{ijv}^* = x_{ijv}^T \beta + z_{ijv}^T b_i + \gamma_v^T \eta_{ij} + e_{ijv} \quad (7)$$

where $\eta_{ij} \sim \text{i.i.d. } N(0, I)$ and is independent of $e_{ij} = (e_{ij1}, e_{ij2}, \dots, e_{ijv})^T \sim \text{i.i.d. } N(0, D)$ (D —diagonal) and of b_i . This reparametrization makes the model an extension of the multivariate generalized linear mixed model^[27,28] that includes ordinal data. Model (7) belongs to the class of generalized linear latent and mixed models (GLLMM)^[29] and hence maximum likelihood estimation can be performed using the *gllamm* function in the software package Stata. However, model (7) has a larger number of random effects than the corresponding model (6) that, in general, requires more computational resources for model fitting.

INTERPRETATION

The regression parameters in the two-level correlated probit model have subject-specific interpretation. To illustrate consider the case of a single predictor variable for all outcomes, for example, say dose. Then the regression coefficients are interpreted as the expected changes in the continuous responses (or latent continuous responses) for a particular subject should dose for this subject be increased by one unit. For binary and ordinal outcomes, these are not the same as the expected changes in the responses for the population as a whole. However, because of the use of the probit link function, the marginal parameters can be obtained from the subject-specific parameters and the variance components parameters.^[30]

This latter point is one of the advantages of using probit models instead of logit models. Another advantage is that with a single random effect and only one observation per level of the random effect, the correlated probit model reduces to the ordinal probit model,^[31] while this is not true for the logit model. In addition, the probit model allows for correlated errors, which is usually an indispensable assumption when multiple variables are involved or when the data are temporally/spatially correlated, while the logit model makes such a generalization difficult.

IMPLIED CORRELATION STRUCTURE

The correlated probit models (6) and (7) are very flexible in accounting for the correlation structure of the data. The variance–covariance matrix between the continuous and latent continuous responses is implied by the underlying multivariate linear mixed model for normal data. Hence, it is very flexible in modeling both multiple variables and spatially/temporally correlated data. These models can be extended to multilevel data following the GLLMM approach and therefore can also accommodate hierarchical sampling designs. Correlations among binary variables and among ordinal variables are estimated by the maximum likelihood estimates of the correlations among the corresponding latent continuous variables and are called tetrachoric and polychoric correlations,^[32] respectively. Correlations between continuous and binary variables, and between continuous and ordinal variables are also estimated by the corresponding latent correlations and are called biserial and polyserial correlations, respectively.^[33]

ESTIMATION IN CORRELATED PROBIT MODELS

General Approaches for Maximum Likelihood Estimation

The focus in correlated probit models has mostly centered on maximum likelihood estimation. Advantages

of likelihood-based procedures include the availability of a well-established inferential framework and flexible treatment of missing data. Methods for maximum likelihood estimation of simple probit models are described by Long,^[34] among others.

Ashford and Sowden^[2] first proposed an iterative procedure for maximum likelihood estimation in bivariate probit models; however, their method was difficult to extend to higher dimensions because of the need to evaluate multivariate normal orthant probabilities.^[6] A simple but not efficient estimation for multivariate probit can be performed by first estimating the regression coefficients by univariate probit and then estimating all unknown elements of the error correlation matrix by considering pairs of responses involving only bivariate normal integrals.

Full information maximum likelihood estimation can be carried out in a direct or indirect fashion. As the marginal likelihood does not have a closed form expression, direct maximum likelihood estimation requires an approximation of the marginal likelihood (or score and information equations) and then an iterative procedure to obtain the maximum likelihood estimates of the parameters. The approximation can be carried out numerically using a method such as Gaussian quadrature^[11,25,35] or stochastically.^[36] Gaussian quadrature is preferred for lower dimensions while stochastic approximations can be used for even higher dimensions. Popular iterative procedures include Newton–Raphson^[37] and Fisher scoring.^[11] Gibbons and Hedeker^[12] extended the marginal maximum likelihood approach to a simple design with three-level data by using non-adaptive Gaussian quadrature for nested integration.

Indirect maximization is typically based on the EM algorithm because if the latent variables are observed then the correlated probit model (5) reduces to a general linear mixed model for normal data. At the E-step of the algorithm, the expectation of the likelihood of the complete data given the observed data and the current parameter estimates need to be approximated and then at the M-step, this conditional likelihood needs to be maximized to update the parameter estimates. The approximations at the E-step can be numerical (for example, Gaussian quadrature),^[16,38] stochastic (for example, Monte Carlo approximation),^[16,19,20] or analytical (for example, Taylor series expansion).^[15]

Special algorithms are available for specific types of the correlation structure for which closed form expressions of the probabilities are available.^[7,14]

Marginal Maximum Likelihood Estimation via Adaptive Gaussian Quadrature

We now provide some detail of marginal maximum likelihood estimation of the correlated probit model (6). Details about the estimation of special cases of that model are provided in Refs. [25,26,39].

By way of example, we consider here the case of two variables, where both response variables are measured at the same occasions. The marginal log-likelihood involves integration over the random effects distribution. Let Ψ denote the vector of all parameters. The marginal likelihood is $\ln L(y; \Psi) = \sum_{i=1}^n \ln L_i(y_i, \Psi)$, where

$$L_i(y_i, \Psi) = \int \prod_{j=1}^{n_i} f(y_{ij1}, y_{ij2} | b_i; \Psi) \times \frac{1}{|2\pi \Sigma_b|^{1/2}} \exp\left(-\frac{1}{2} b_i \Sigma_b^{-1} b_i\right) db_i$$

As the integral does not have a closed form expression when at least one binary or ordinal response variable is present, we need to use an approximation. When the dimension of the random effects vector is not large (up to four or five) we can use adaptive Gaussian quadrature as implemented in PROC NLMIXED in SAS.^[40] The *general* statement in PROC NLMIXED allows one to explicitly write the log-likelihood in the integrand as long as analytical expression is available.

When both response variables are binary, then

$$f(y_{ij1}, y_{ij2} | b_i) = \prod_{k=0}^1 \prod_{l=0}^1 P(y_{ij1} = k, y_{ij2} = l)^{I(y_{ij1}=k, y_{ij2}=l)}$$

where each of these normal quadrant probabilities is obtained as shown for model (4) and the parameter vector is omitted for simplicity of notation. For example

$$P(y_{ij1} = 0, y_{ij2} = 0) = P(y_{ij1}^* < 0, y_{ij2}^* < 0) = \Phi^{(2)}(-lp_{ij1}, -lp_{ij2})$$

where

$$lp_{ij1} = x_{ij1}^T \beta + z_{ij1}^T b_i \quad \text{and} \\ lp_{ij2} = x_{ij2}^T \beta + z_{ij2}^T b_i$$

When both response variables are ordinal, the conditional likelihood is similarly handled, and details are provided by Grilli and Rampichini.^[26]

When one response variable is continuous and one is ordinal (binary) we can rewrite the joint conditional density of the bivariate response given the random effects as the product of the univariate normal density of the continuous outcome $y_{ij1} | b_i$ and the conditional multinomial density of the ordinal outcome $y_{ij2} | y_{ij1}, b_i$. That is

$$\begin{aligned}
f(y_{ij1}, y_{ij2} | b_i) &= f_1(y_{ij1} | b_i) f_2(y_{ij2} | y_{ij1}, b_i) \\
f_1(y_{ij1} | b_i) &= \frac{1}{(2\pi\sigma_{\varepsilon 1}^2)^{1/2}} \exp \left\{ -\frac{1}{2\sigma_{\varepsilon 1}^2} (y_{ij1} - lp_{ij1})^2 \right\} \\
f_2(y_{ij2} | y_{ij1}, b_i) &= \Phi \left(\frac{\tau_1 - lp_{ij2}^*}{\sigma^*} \right) I(y_{ij2} = 1) \\
&\quad \left\{ \Phi \left(\frac{\tau_2 - lp_{ij2}^*}{\sigma^*} \right) - \Phi \left(\frac{\tau_1 - lp_{ij2}^*}{\sigma^*} \right) \right\}^{I(y_{ij2}=2)} \dots \\
&\quad \left\{ 1 - \Phi \left(\frac{\tau_{D-1} - lp_{ij2}^*}{\sigma^*} \right) \right\}^{I(y_{ij2}=D)}
\end{aligned}$$

where

$$\begin{aligned}
lp_{ij1} &= x_{ij1}^T \beta + z_{ij1}^T b_i, \\
lp_{ij2} &= x_{ij2}^T \beta + z_{ij2}^T b_i + \sigma_{\varepsilon 12} / \sigma_{\varepsilon 1}^2 (y_{ij1} - lp_{ij1}), \quad \text{and} \\
\sigma^* &= \sqrt{1 - \sigma_{\varepsilon 12}^2 / \sigma_{\varepsilon 1}^2}
\end{aligned}$$

In theory, this approach is extended to the case of multiple binary, ordinal, and continuous outcomes by specifying the multivariate conditional density of the observed continuous outcomes and then conditional on the continuous outcomes specifying a multinomial likelihood for all binary and ordinal outcomes, with category probabilities obtained using the multivariate normal cumulative density function. In practice, this approach works only with at most two ordinal responses, because of software limitations (SAS functions exist to calculate bivariate, but not higher order multivariate normal probabilities). The approach easily extends to modeling the variances and covariances of the random effects and/or errors as functions of the variables in the model. The three-level formulation of the model can be fitted using *gllamm* in Stata and is more flexible in handling randomly missing data.^[25,26]

Both the two-level and the three-level approaches are limited to about four-dimensional random effects and/or random error distributions because adaptive Gaussian quadrature becomes either computationally exhaustive or intractable. Alternative simulation methods based on the EM algorithm can be used for estimation.^[19]

Other Types of Estimation

Because of the complexity of full information maximum likelihood, a number of authors have considered alternative estimation methods. Muthen^[41] handled more than two response variables by using limited information generalized least squares and implemented the solution by Fisher scoring. Regan and Catalano^[22] and Geys et al.^[23] used GEE to fit correlated probit models for mixed continuous

and discrete outcomes. Spiess and Hamerle^[42] also considered GEE but supplemented with pseudoscore equations for association parameters. Qu et al.^[43,44] estimated both regression and association parameters using GEE. Spiess^[45] compared via a Monte Carlo experiment the latter three approaches and showed that the Spiess and Hamerle estimate is most efficient among non-ML estimates. Chib and Greenberg^[46] developed practical simulation-based Bayesian and non-Bayesian analysis of correlated binary data. Dunson, Chen, and Harry^[24] considered a fully Bayesian approach. Avery, Hansen, and Hotz^[47] developed quasi-maximum likelihood methods under temporal correlation and certain orthogonality conditions.

Software for fitting generalized linear mixed models can be used when all outcomes are of the same type and when the errors are assumed uncorrelated. Methods for fitting generalized linear mixed models are described by McCulloch and Searle,^[8] Diggle, Liang, and Zeger,^[48] Fahrmeir and Tutz,^[49] and Agresti.^[50]

INFERENCE

As mentioned above, one of the advantages of likelihood-based procedures include availability of well-established inferential framework. Thus, nested models can be compared using likelihood ratio tests. The significance of regression parameters and variance components not on the boundary can be tested using likelihood ratio, Wald or score tests. Testing of variance components on the boundary is more problematic because the asymptotic distribution is no longer chi-square. Comparison of models with different covariance structures can be based on information criteria, such as Akaike information criterion and Schwartz Bayesian criterion. Alternatively, if Bayesian analysis is undertaken, Bayes factors can be employed.^[46]

EXAMPLE

Developmental Toxicity Application^[51]

This was a study to examine the teratogenic effects of ethylene glycol conducted by the National Toxicology Program. During organogenesis pregnant mice were exposed to ethylene glycol at one of four different dose levels: 0, 0.75, 1.5, and 3 mg/kg. Fetal weight and a binary malformation indicator for each fetus j within litter i , and litter size s_i were recorded. It was of interest to estimate the dose effect on adverse outcomes (malformation and low fetal weight). Descriptive statistics for the developmental toxicity data are available in Table 1. These data were previously analyzed by many authors.^[14,17–19,24,25]

Although litter size is not considered an adverse outcome per se, we choose to model it herein together with fetal weight and malformation because of the potential estimation

Table 1 Descriptive Statistics for the Developmental Toxicity Study in Mice

Dose (mg/kg)	Dams	Mean litter size	Range litter size	Mean fetal weight	SD of fetal weight	Number malformed	Percent malformed
0	25	12.16	7–16	0.972	0.098	1	0.34
0.75	24	11.71	7–15	0.877	0.104	26	9.42
1.50	22	10.45	1–15	0.764	0.107	89	38.86
3.00	23	10.13	4–14	0.704	0.124	126	57.08

bias when it is ignored^[24] and because we would like to illustrate the use of the correlated probit model in a complicated design, involving a mixture of binary, ordinal, and continuous variables at different levels of nesting. We now consider a variation of the model of Gueorguieva^[25] with a correlated probit formulation for litter size. This is also the most general model, which was considered in conference paper.^[52]

$$\text{Weight}_{ij} = \alpha_1 + \beta_1 \text{dose}_i + b_{i1} + \varepsilon_{ij1}$$

$$\text{Latent Malf}_{ij} = \alpha_2 + \beta_2 \text{dose}_i + b_{i2} + \varepsilon_{ij2}$$

$$P(\text{Litter size}_i = k | b_i) = \Phi(\tau_k - \beta_3 \text{dose}_i - b_{i3}) - \Phi(\tau_{k-1} - \beta_3 \text{dose}_i - b_{i3})$$

$$\begin{pmatrix} b_{i1} \\ b_{i2} \\ b_{i3} \end{pmatrix} \sim \text{i.i.d. } N \left(\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}, \begin{pmatrix} \sigma_{b1}^2 & \rho_{b12}\sigma_{b1}\sigma_{b2} & \rho_{b13}\sigma_{b1} \\ \rho_{b12}\sigma_{b1}\sigma_{b2} & \sigma_{b2}^2 & \rho_{b23}\sigma_{b2} \\ \rho_{b13}\sigma_{b1} & \rho_{b23}\sigma_{b2} & 1 \end{pmatrix} \right)$$

independent of

$$\begin{pmatrix} \varepsilon_{ij1} \\ \varepsilon_{ij2} \end{pmatrix} \sim \text{i.i.d. } N \left(\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} \sigma_{\varepsilon1}^2 & \rho\sigma_{\varepsilon1} \\ \rho\sigma_{\varepsilon1} & 1 \end{pmatrix} \right)$$

We assume a random intercept for each variable and that these intercepts are correlated. This formulation implies an exchangeable correlation structure for each variable; that is, the correlation between fetal weight as measured on two fetuses within the same litter is constant and similarly, the correlation between latent malformation (i.e., malformation indicator) as measured on two fetuses within the same litter is also constant. We assume that there is a random intercept for litter size for convenience of modeling the correlation structure of the data.

Explicit in the model formulation are the necessary restrictions for theoretical and empirical identifiability of the model. Namely, the variance of the random effect for

litter size is assumed to be equal to 1, the error variance corresponding to the binary malformation variable is assumed to be equal to 1, and there is no intercept for the cluster level variable, litter size. Because of the correlated probit model formulation for litter size we also need to assume that the thresholds are ordered: $\tau_1 < \tau_2 < \dots < \tau_{D-1}$. Litter size ranges from 1 to 16; however, some litter sizes are not present and hence we estimate threshold parameters only for the litter sizes available in the data set.

The above model was fitted using PROC NL MIXED in SAS, and the results are presented in [Tables 2](#) and [3](#). Fetal weight and litter size decrease with dose while individual's probability of malformation increases with dose ([Table 2](#)). These findings are not surprising and, in a similar form, can be obtained by performing marginal analysis of each variable. However, marginal analyses will not give information about the correlation structure of the data and will not allow estimation of the probability of at least one adverse event (either low fetal weight or malformation), which is of considerable interest in risk assessment.

Based on the results in [Table 3](#), there is a significant positive correlation between fetal weight measured on two different fetuses within a litter and between malformation measured on two different fetuses within a litter. There was also negative correlation between fetal weight and malformation, whether measured on the same or on different fetuses within a litter, as well as between weight of a fetus within a litter and litter size. The latter result is intuitive because the more fetuses there are within litter, the more likely it is that the fetuses will be smaller. It is interesting however that the negative association between fetal weight and malformation observed in the raw data persists even after dose is controlled for in the model. Contrary to the finding concerning fetal weight there is no correlation between malformation and litter size.

Although the model we considered is quite general, there are still other potential extensions that can be considered. For example, the variances and covariances can be modeled as functions of the dose.

While the exchangeable correlation assumption does not appear restrictive in this data example with litter as the clustering variable, it is usually not appropriate for longitudinal data where random slopes are commonly assumed in addition to random intercepts and where special structures of the error variance–covariance matrix (e.g., autocorrelated) may be appropriate.

Table 2 Maximum Likelihood Estimates for the Parameters in the Developmental Toxicity Study in Mice

Response variable	Parameter	Maximum likelihood estimate (SE)
Fetal weight	Intercept (α_1)	0.944 (0.015)
	Dose (β_1)	−0.087 (0.009)
	SD ^a of random intercept (σ_{b1})	0.089 (0.007)
	SD ^a of random error (σ_{e1})	0.095 (0.002)
Malformation	Intercept (α_2)	−2.307 (0.198)
	Dose (β_2)	0.915 (0.102)
	SD ^a of random intercept (σ_{b2})	0.779 (0.098)
	SD ^a of random error (σ_{e2})	1.00 (0.00) ^b
Litter size	Dose (β_3)	−0.384 (0.136)
	SD ^a of random intercept (σ_{b3})	1.00 (0.00) ^b

^aSD denotes standard deviation.

^bThese parameters are fixed at the value of 1 for identifiability.

Table 3 Maximum Likelihood Estimates for Correlations between Response Variables in the Developmental Toxicity Study in Mice

Level	Variable 1	Variable 2	Maximum likelihood estimate (SE)
Within <i>i</i> th litter	Fetal weight on <i>j</i> th fetus	Fetal weight on <i>k</i> th fetus	0.47 (0.04)
	Malformation on <i>j</i> th fetus	Malformation on <i>k</i> th fetus	0.38 (0.06)
	Fetal weight on <i>j</i> th fetus	Malformation on <i>k</i> th fetus	−0.27 (0.05)
	Fetal weight on <i>j</i> th fetus	Malformation on <i>j</i> th fetus	−0.29 (0.06)
Between <i>i</i> th litter size and variables measured in <i>i</i> th litter	Size of <i>i</i> th litter	Fetal weight on <i>j</i> th fetus	−0.21 (0.07)
	Size of <i>i</i> th litter	Malformation on <i>j</i> th fetus	−0.04 (0.09)

SOFTWARE

In the early 1990s, Lessafre and Molenberghs^[32] observed that multivariate probit analysis was a neglected procedure in medical statistics because of the lack of software to perform such analysis. Therefore, they created an MS-DOS program for variable selection and model fitting of bivariate probit models. Owing to the recent computational advances, there are now several programs that can be used to fit more sophisticated probit models in higher dimensions. We already demonstrated how the popular SAS PROC NLMIXED can be used for a complicated example. The *gllamm* function in Stata^[29,53] can be used for the same model, and unlike PROC NLMIXED it can handle multilevel models. Preisler^[54] performs marginal maximum likelihood using Gaussian quadrature employing GLIM, while MIXOR was especially created for random effects analysis of repeatedly measured ordinal outcomes. Gibbons^[55] provides a nice description of the MIXOR implementation and lists additional software for binary, ordinal, and continuous data.

CONCLUSIONS

In this entry we presented a description of correlated probit models and demonstrated how such models can be fitted using standard software. Historically, probit models have not been as popular as logit models mainly because of the lack of odds-ratio interpretation and the computational difficulties in obtaining estimates for such models. However, probit models have appealing interpretation in the context of an underlying continuous response, and the computational problems have been minimized in recent years. Unlike logit models, probit models seamlessly allow for specification of correlated errors, which is an important and often indispensable assumption for spatial or temporal data. In addition, there is a direct correspondence between multivariate and univariate probit models, correlation structure modeling is flexible, and there is a convenient relationship between subject-specific and marginal model parameters. Hence, the correlated probit model has undergone a dramatic change from a “neglected procedure in medical statistics” into an accepted and useful model for correlated data.

ACKNOWLEDGMENT

I wish to thank Mr. Brian Pittman for his helpful comments.

Cost-Effectiveness Analysis

Heejung Bang

University of California, Davis, California, U.S.A.*

Abstract

Effectiveness and cost are the key components when comparing health-care options and making treatment decisions. Cost-effectiveness analysis (CEA) is the methodological approach that informs this evaluation. In this entry, we review the basic concepts and statistical methods, which are the foundations of CEA, and discuss quantitative and qualitative issues, which are quite unique to CEA.

Keywords: Cost-effectiveness; Clinical trial; Health outcome; QALY; Willingness to pay.

INTRODUCTION

It was an expensive way to live, so I decided to look for cheaper lodgings. But how do you find comfortable rooms at a reasonable price?

—Dr. Watson (*The Adventures of Sherlock Holmes*)

The rising economic burden of health care is a significant concern across the globe, particularly in countries with aging populations and inflated costs associated with the development, testing, marketing, and distribution of the new therapeutic and technological interventions. Most societies seek to provide the best or affordable health care to their citizens, often with very limited resources.

Cost had played an important role even in the presumably first controlled clinical trial of the modern era. Although the effect of oranges and lemons was apparent on the cure of scurvy, James Lind (1716–1794) hesitated to recommend them because they were too expensive. Nearly 50 years after, the British Navy eventually made lemon juice a part of the diet and was replaced by lime juice because it was cheaper.

Many interventions/regimens that are widely used in usual care or daily practice e.g., vitamin C, aspirin, chlorination of water, antibiotics, birth control pill, insulin, antiretroviral therapy, etc., produce large treatment effects. However, such discoveries are rare, so that research results often point to innovations with smaller effects or encourage the use of existing interventions for different target populations or goals, such as personalized medicine to identify an optimal therapy, dose or subgroup, or off-label use. The reality is that it is a long and expensive process to develop a new intervention (drug, treatment, technology, program, and policy) that is

significantly better than standard care, and this impacts greatly on cost relative to perceived health benefit. A notable example is a cancer drug that extends survival by 1.2 months at a cost of \$80,000.^[1] Efforts are made not only to develop interventions that could be comparable to standard care in terms of efficacy or cost but also to convey other advantages in terms of accessibility, tolerability, or convenience.

In the quest to determine which intervention produces the greatest value, cost is a commonly adopted outcome, secondary to the primary clinical outcome. Cost is a factor in virtually all comparative outcomes and decisions. Cost-effectiveness analysis (CEA) compares the relative expenditures and outcomes of competing strategies, with a goal to identify which provides the maximum aggregate health benefit for a given level of resources—or, equivalently, which provides a given level of health benefit at the lowest cost.

In this entry, we review the statistical methods used in CEA and discuss related concepts, quantitative and qualitative issues, and controversies that are somewhat unique to CEA. A previous version of this entry provides a general overview from economics perspectives;^[2] this newer version focuses on statistical methods and concepts that may be useful to practitioners and statisticians who may not specialize in health economics. Various journals, websites, and textbooks provide guidelines on the conduct and presentation of CEA. However, unlike effectiveness analysis (EA) in which consensus on methodology and implementation has been reasonably well established (enabling regulatory agencies, pharmaceutical companies, clinicians, and researchers to learn and use the same or well-agreed methods and data, while permitting reasonable flexibility), there are additional challenges and nuances associated with CEA.

STATISTICAL MEASURES

Let C_i and E_i denote cost and effectiveness for i th group, respectively, $i = 1$ (new), 2 (standard or control), where two interventions are compared head-to-head:

- If $E_1 > E_2$ and $C_1 < C_2$, new is more effective and less costly (dominate; accept)
- If $E_1 < E_2$ and $C_1 > C_2$, new is less effective and more costly (dominate; reject)
- If $E_1 > E_2$ and $C_1 > C_2$, new is more effective and more costly (trade-off)
- If $E_1 < E_2$ and $C_1 < C_2$, new is less effective and less costly (trade-off)
- If $E_1 \approx E_2$, compare C_1 and C_2 (cost minimization)
- Compare E_1 and E_2 (EA)

The scenarios above can be visualized in a cost-effectiveness (CE) plane, and CEA is particularly relevant when a new intervention is more effective and more costly. The International Society for Pharmacoeconomics and Outcomes Research (ISPOR) Task Force (2005) recommended that CEA be performed even when clinical effectiveness fails to be demonstrated. This is an ideal recommendation and indeed $E_1 \approx E_2$ is the goal of equivalence testing (e.g., generic drug); yet, some mathematical challenges could be entailed, as described below.

CE Plane

The CE plane is a simple, intuitive graphical tool that presents the difference in effectiveness (in X-axis) and the difference in cost (in Y-axis) between two interventions in the four quadrants (see Fig. 1a).^[4] The CE plane is essential for any CEA to prevent numerical or interpretational error (e.g., 2/2 vs. -2/-2), similar to descriptive statistics as a prerequisite for any data analysis. The CE

plane can be used with a point estimate of the incremental cost-effectiveness ratio (ICER), along with bootstrapped versions that can characterize its sampling variability and confidence interval (CI). Furthermore, the five decision regions in the CE plane may be used as a reference figure or yardstick to assist the final judgement. (see Fig. 1b). Of note is that the parameter and estimator in notation are not distinguished.

ICER

The most widely adopted measure in CEA is the ICER. Trade-off through “increment” (relative, marginal, or net) denoted by Δ is a key concept and parameter in economics. The ICER is defined as $\Delta C / \Delta E$. It is interpreted as additional cost needed to improve effectiveness (of a continuous variable or count) by 1 unit and conventionally estimated by:

$$\text{ICER}_{\text{mean}} = \frac{\text{mean}(C_1) - \text{mean}(C_2)}{\text{mean}(E_1) - \text{mean}(E_2)} \quad (1)$$

If effectiveness is binary (e.g., cure or no cure), its expected value or mean becomes the probability. The ICER also is resulted from a maximization problem with the Lagrange multiplier.

After computing the ICER, its value could be compared with the willingness to pay (WTP) for a 1-unit increment in E, denoted by λ (lambda), which serves as the ICER threshold. A sample decision is if $\text{ICER} < \lambda$, then the new intervention is cost-effective, not otherwise. More discussions on λ are provided below. The ICER can be interpreted as slope from (0,0) to (x,y) on the CE plane. Some analysts create a “league table” using the ICERs for ranking purposes.^[5]

Some measures utilize specialized names but can be understood within the ICER framework. For example,

Fig. 1 Cost-effectiveness plane (a: left) with five decision regions (b: right)

Source: (b) Reproduced from Obenchain.^[3] ©2008 by permission of the author and copyright holder.

“cost per case prevented” is the difference in cost between the two interventions divided by the associated difference in the number of cases of a bad event.

Incremental Net Benefit (INB)

Despite wide acceptance and popularity, the ICER has some methodological weaknesses. First, ICER as a ratio statistic of the two differences can be $\pm$ infinity when the denominator (=difference in effectiveness) is 0, in which case CI construction could be troublesome. Also, the two totally opposite results (e.g., 2/2 vs. $-2/-2$) can have the same ICER, and negative ICERs are difficult to interpret and may not be properly ordered.^[6]

An alternative way to view the ICER is that overall outcome pairs are standardized by expressing both of their components in the same units. With the help of λ , the ICER threshold, the ICER can be expressed as $(x,y) = (\lambda\Delta E, \Delta C)$ or $(\Delta E, \Delta C/\lambda)$, naturally connecting the ICER can be expressed with the notion of (net) benefit (see sample calculations of different measures in Table 1). $INB = \lambda\Delta E - \Delta C$ overcomes the ICER’s limitations and puts E and C in the additive/linear scale, conveying improved statistical properties. As is clear in the formula, INB is a function of λ , a generally unknown constant, which is desired but not required when we use ICER. If $INB > 0$, we conclude that the net benefit of an intervention exceeds the cost or that the new treatment is cost-effective; virtually, the same rule is used for ICER and INB. INB (in Y-axis) as a function of λ (in X-axis) can be drawn in a figure—along with CI or band—over plausible values of λ .

CE Acceptability Curve

Another variant of ICER or INB is cost-effectiveness acceptability curve (CEAC). A plot can be drawn with X-axis = λ and Y-axis = $P(INB > 0)$ across a range of λ , and it can show the estimated probabilities that the new treatment is cost-effective for different values of WTP.^[7]

Average Cost-Effectiveness Ratio (ACER)

A simple and intuitive measure that has been used in cost analysis and CEA is the ACER:

$$ACER_i = \frac{\text{mean}(C_i)}{\text{mean}(E_i)} \quad (2)$$

Some interpret ACER as ICER when the control group offers zero effect and zero cost. Not using “relative” measure leads some to reject the use of the ACER or to limit its use to restrictive or simplistic CEA contexts (e.g., non-competing choices).^[2,8–10]

Some properties of ACER might be appealing from statistical perspectives as exploratory or supporting measures. For instance, ACER is well defined for one or more groups and accords with the traditional framework of estimation and testing for single or multiple groups, whereas ICER requires a comparator (and unknown threshold λ). The Neyman–Pearson hypothesis testing paradigm and its role in efficient allocation provide some theoretical support for ACER.^[11] Also, the ACER’s denominator is further from zero, so its point and CI estimates tend to be numerically stable.

Various measures based on the notion of “cost per case (or patient)” might be viewed within the ACER framework. For example, “cost per (usable) response” is used in survey research and “cost per patient in care” is used in HIV care.^[12,13]

DESIGN, METHODS, AND STATISTICS-RELATED ISSUES

Types of CEA; What is in the Denominator?

The basic steps in any CEA are to identify, measure, value, and compare costs. How to define cost(s) for a single person (raw or individual patient data) is the first step in any cost-related analysis. However, *do we really know what costs how much?* Inherently, the complete enumeration of each cost component and identification of a correct/accurate cost are complicated and quite subjective processes. Oftentimes, the cost for the i^{th} patient, C_i , must be estimated with high uncertainty, unlike E_i , which can be measured in a more objective or standardized fashion (e.g., survival time, response, blood pressure, and depression) in the EA. Inclusions/exclusions of various cost contributors

Table 1 Sample calculations of cost-effectiveness ratios and net benefits

Treatment alternative	Cost	Effect (anxiety-free weeks)	Cost-effectiveness ratio	Monetary value of the effect (or benefit)	Net benefit
Standard	\$1,000	40	ACER = \$25	$\lambda E = 20,000$	NB = 19,000
New	\$2,000	50	ACER = \$40	$\lambda E = 25,000$	NB = 23,000
Difference (Δ)	\$1,000	10	ICER = \$100	$\lambda\Delta E = \$5,000$	INB = 4,000

Note: ACER = average cost-effectiveness ratio; ICER = incremental cost-effectiveness ratio; INB = incremental net benefit; NB = net benefit; λE = the monetary value of effect is benefit ($B \equiv \lambda E$). (Remark: Outcome in natural units = effect, and monetary value = benefit = effect (in units) $\times$ value per unit.) Here, we have artificially assumed that societal willingness to pay for patient outcome (λ) equals \$500 per anxiety-free week. NB = monetary value of effect – cost; INB is calculated with an assumed value of $\lambda = \$500$; effect difference $\times$ \$500 – cost difference.

Source: Adapted from Hoch and Dewa.^[7] ©2008.

and time period substantially impact on the final estimate and analysis of costs. How to determine cost is not really a statistical question; sources and methods to be used (such as, reimbursement, cost-to-charge ratio, consumer price index, microcosting, top-down vs. bottom-up, etc.) are in the domains of economics and finance. Of note is that the cost estimates can be highly dependent on the method used.

Once a patient-level total cost—assumed to be independent and identically distributed over different individuals, while (longitudinal/intermediate) costs within individual are correlated—is derived, the next step is to estimate the population summary measure. A fundamental statistical parameter is $E(C)$, representing the expected value or mean of a variable C_i , where C denotes cost and i indexes individuals here. Oftentimes, $E(C)$ per se is of primary interest, for instance to estimate the cost of colorectal cancer. In the CEA, the arithmetic mean of costs in the untransformed/original scale is the primary parameter.

Within the same ICER formula, we use different names depending on what constitutes the denominator. To list, “cost minimization” is simply to compare the costs in two groups, ignoring the denominator (effectiveness), particularly when the denominator is close to 0. [Of note is, the seamless use of ICER with the CE plane in a unified framework, whether the denominator is 0 or not (which is not always apparent to determine), has been proposed.^[14]] When we use clinical outcomes such as survival time or life years (LY) for the effectiveness measure, it is called the CEA. Alternatively, if we use quality-adjusted life year (QALY) in place of LY, then a more specialized term will be the cost-utility analysis (CUA). As QALY is regarded as the most widely recommended measure of effectiveness, many use CEA and CUA interchangeably. QALY seeks to combine multidimensional consequences of health status into a one-dimensional metric with health utilities—a weight of 0 for death and 1 for perfect health. This approach is especially useful for interventions that extend life but at the expense of side effects or lower quality or that reduce morbidity instead of mortality. When the effectiveness is converted into monetary values, it is called the cost-benefit analysis (CBA). This analysis allows the numerator and denominator to take same scale/unit, so that health-related programs and policies may be more easily compared. CBA provides a clear decision rule—undertake an intervention if the monetary value of its benefit exceeds its cost. However, due to a general reluctance to characterize health benefits in monetary terms, CUA and CEA are more popular.

Study Design: Experiment Trumps Observation?

A (well-designed and conducted) randomized controlled trial (RCT) is scientifically the best study design for EA in practice, wherein a “head-to-head” on average comparison can be achieved. However, whether this is also the gold standard for CEA is questionable. The RCT design aims to

compare A versus B for a relatively short term on a homogeneous population, generally involving lengthy inclusion/exclusion criteria and protocol-driven tests for research purposes. Thus, generalizability of the findings to the real-world or usual practice in a broader population may be limited. While RCTs can minimize confounding and selection biases, it may not be superior in other aspects, such as valid and meaningful cost estimates. Also, new drug acquisition price is *unknown* at the clinical trial stage. Observational evidence (e.g., obtained from registry, medical records and expert opinions on actual medical practice) is inevitable in CEA, often with heavily assumption-driven modeling.

Skewness

As cost data tend to be highly skewed, so is the ICER. Thus, in addition to the mean, which is the norm, other summary measures and non-parametric approaches (e.g., median, quartiles, log-transformation, and bootstrap instead of Fieller for a CI) have been used. Consideration related to data distribution should be given. When cost data are log-transformed, it has been reported that an incorrect hypothesis is frequently used.^[15] Standard non-parametric methods, analyses of transformed costs and measures other than the arithmetic mean, are generally deemed inappropriate in CEA because the cost of treating all patients is needed as the basis for health-care policy decisions.^[16] Notwithstanding, the use of nonparametric methods for skewed or non-normal data may be practically unavoidable due to their dominance; e.g., the Wilcoxon test instead of (standard or bootstrap) t-test for cost comparison. Supporting roles of median/quantile-based methods for cost data also have been suggested; for instance, mean versus median-based analyses can yield meaningfully different results, in which case a conclusion may not be readily available, e.g., more evidence is needed.^[14,17]

In addition, median survival time has been regarded as a preferred outcome measure in the EA and statistics literature (due to mathematical issues), as long as it is estimable with time-to-event or survival data, say, when the Kaplan–Meier curve reaches 0.5.^[18] Thus, there are discrepancies in key parameters in EA versus CEA—median survival time for EA and mean survival time or QALY for CEA.^[19]

Discounting

Cost is meaningful only with an accompanying reference year (and location). When we deal with costs that accumulate across time, conversion is generally utilized. Discounting is justified because people tend to prefer dollars today versus dollars in the future (even with zero inflation). CEA usually incorporates this time preference that includes dollars over more than 1 year. Annual discount rates of 3% and 5% are the most popular choices for cost, while other rates are considered in sensitivity analyses. Similar to cost, people tend to want current health more

than future health. Discounting in health effect and the inflation in cost (which is distinct from discounting) are less often agreed upon.^[5,20,21]

Censoring

A common effectiveness measure in prospective health studies is time-to-event, e.g., survival time/LY or QALY. When survival time is censored, i.e., the patient did not die by the end of observation or follow-up period, the associated cost is also censored such that the observed cost is merely a lower limit of the true cost. Censoring complicates statistical analyses and should be adjusted. Indeed, censoring is routinely adjusted in EA in practice, which is why we use the Kaplan–Meier estimate or the Cox model. Moreover, censoring could influence a parameter’s identifiability or estimability and may determine which parameter should be primary. For example, the mean cost and mean survival time, the two key components in the CEA, are not always estimable with censored data. As a remedy, the *restricted* mean is often used and its theoretical issues have been studied in the statistical literature.^[22] The underlying mechanism calling for special attention is that, even when censoring is uninformative (or random) for survival time (which is assumed in most EA), censoring is *informative* for cost, due to the positive correlation between cost at event of interest and cost at censoring. Interestingly, this informative, induced censoring also happens to QALY. As such, cost and QALY may be mathematically more similar than are LY and QALY in some aspects. Thus, most standard survival analyses (e.g., Kaplan–Meier) are valid for censored survival data but not for censored cost or QALY

data. Various mean cost and ICER estimators with censoring have been proposed.^[22,23]

Modeling and Sensitivity Analyses

It was previously stated that RCT may not be the gold standard for CEA. Moreover, individual patient data for long term are often unavailable. In these circumstances, an alternative approach is decision analytic modeling, especially when we are interested in lifetime cost. Decision modeling compares the expected costs and consequences of decision options by synthesizing information from multiple data sources and applying mathematical techniques, usually with computer software.^[24] Modeling (e.g., Markov model, decision tree, and simulation) can be used where inputs are provided from best available sources, including concurrent or existing data and literature (see Fig. 2).^[20,24] Careful design and planning, along with a protocol documenting data sources, methods, assumptions, and sensitivity analysis (including substantially different perspectives, short vs. long term, and best vs. worst case scenarios), are critical.

Models and results should be sensible, transparent, reproducible, and well documented. Modeling results are only as good as: 1) the data inputs provided to the model; 2) the structure of the model; and 3) correct implementation. It has been demonstrated that different models, such as new vs. old (standard) model with one outdated component (i.e., assumption 9), can produce the estimates with a 10 times difference in a nutritional modeling and prediction.^[25] Wrong assumptions and investigator biases (e.g., protocol not fully prospective, unblinded) are big

threats in modeling, although the choices and mistakes made can be honest.

An economic study from a cardiovascular RCT presented actual/estimated ICERs and projected ICERs over time—actual follow-up of the first 3.5 years and projecting it for 12 years under three hypothetical scenarios (see Fig. 3).^[26] This kind of plot may serve as a good example in CEA, demonstrating that trial-based (utilizing individual patient data) and modeling-based economic evaluations can be complementary.

Budget Impact Analysis as Companion

Budget impact analysis (BIA) may be required by reimbursement authorities, along with a CEA, as part of a listing or reimbursement submission or freestanding economic evaluations for budget or resource planning. A BIA addresses the expected changes in the expenditure of a health-care system before versus after the adoption of a new intervention. The ISPOR Task Force provided a reporting guide on BIA in 2007 and an update in 2014. Similar methodological issues covered in this entry are applied to BIA and CEA, including perspectives, types of costs, time horizon, discounting, input and data sources, uncertainty, and validation.

Sample Size

Every study needs sample size (N) and statistically supported sample size is always preferred whenever possible. Naturally, calculation of N for economic evaluation shares much in common with calculation of N for efficacy/

effectiveness evaluation, and a sizable number of publications and formulae are available to guide N adequate for a given CEA (see Glick for sample formulae and literature review).^[27] A goal of N/power calculation for CEA can be to identify the likelihood that an experiment will allow us to be confident that a therapy has a good or bad value when we adopt a particular WTP.

However, it is easily visible that the complexity associated with sampling uncertainty for economic assessments (e.g., standard deviation of cost) and methodological issues and choices (e.g., cost comparison only vs. ICER vs. INB, which threshold, hypothesis testing vs. estimation) can complicate these N calculations. It is reasonable to expect to assume N required for CEA is generally larger, more vague (thus, justifying it as “rule of thumb”), compared to the EA counterpart. Oftentimes, trialists do not have a sufficient power/N for a primary hypothesis testing in the EA, which can render CEA more underpowered. Moreover, it may not be ethical to accrue a larger number of patients for a well-powered CEA, which is generally a secondary aim in clinical trials. These issues further justify the pragmatic necessity of (very) large databases for economic studies, outside or beyond clinical trials, despite other limitations.

CONTROVERSIES

CEA or Not; QALY or Not?

The Patient-Centered Outcomes Research Institute (PCORI) was established by the 2010 Patient Protection and Affordable

Fig. 3 ICER over years: Actual and projected connected for short vs. long terms

Source: Reproduced from Zwanziger et al.^[26] ©2006 Elsevier.

Care Act in the United States. It provides methodology guidelines such as:

The Patient-Centered Outcomes Research Institute ... shall not develop or employ a dollars per quality adjusted life year (or similar measure that discounts the value of a life because of an individual's disability) as a threshold to establish what type of health care is cost effective or recommended. The Secretary shall not utilize such an adjusted life year (or such a similar measure) as a threshold to determine coverage, reimbursement, or incentive programs under title XVIII. (The Patient Protection and Affordable Care Act)

In brief, the PCORI did not approve CEA and the use of QALY. Banning the use of a specific analysis or metric is quite unusual. In comparison, in 1996, the first U.S. Panel on Cost-Effectiveness in Health and Medicine (composed of physicians, health economists, ethicists, and other health policy experts) after 2 years of deliberation, recommended that CEA should use QALY as a standard metric to identify and assign value to health outcomes.^[28,29] Furthermore, the UK National Institute for Health and Care Excellence determines CE directly based on QALY valuations. Although it is understood that varying policies, processes, and decisions exist across different countries, agencies, and times, the PCORI's decision demonstrates how controversial CEA and its key measure can be.

In the CEA community, QALY is recommended and used in the "reference case" analysis. In contrast, in the EA community, QALY is rarely chosen as a primary outcome. Adding to this discrepancy in reporting, converting thousands of potential clinical outcomes (in natural health units) into QALY format and establishing consensus are formidable or nearly infeasible.

Which Perspective?

Total cost and CEA depend on the stakeholders' perspectives. Although the perspectives of society, institution, payer, and patient are all important, the societal perspective carries the most weight for policy decisions. From the comprehensive societal viewpoint that is relevant to all affected parties, all potential costs—direct, indirect, hidden, or opportunity—should be considered, regardless of who pays the costs or who receives the benefits. Patient- and institution-centered perspectives or ascertainment of actual costs spent/incurred, which is more explicit and objective, may provide additional information for ancillary or sensitivity purposes.

The Second U.S. Panel on Cost-Effectiveness in Health and Medicine (formed in 2012 and revised recommendations published in 2016) recommended that all CEA should report two reference case analyses—one based on a health-care sector perspective and another based on a societal perspective.^[29] Along the line, the Panel provided an "impact inventory," which is a structured table that contains consequences (both inside and outside the formal health-care sector), to clarify the scope and boundaries of the two reference case analyses.

Silence of λ , in the Eye of Policy Maker?

λ , the WTP, has both a positive property (it is a constant) and a negative property (it is arbitrary, unknown, and silent).^[3,30] The most frequently cited numerical value for λ is \$50,000 for one additional QALY gained. Other thresholds have been used, such as £3* \$100 K, CAN \$20 K, UK £20 K, among others. Ubel questioned the price of life and why it doesn't increase at the rate of inflation.^[31] Furthermore, it may be unlikely that \$50,000 per QALY is consistent with societal preferences in the modern medicine. Naturally, the criteria for judging CE are different at different times and in different places.

One versus Multiple Methods and Analyses?

In the CEA context, according to Hoch,^[10] "Published articles may be rejected by certain journals in part because of a reviewer's disagreement with the CEA methodology ... As studies that use CEA continue to proliferate, this conflict is sure to reach a flash point ... Journal editors may be forced to moderate methodological disagreements." On the other hand, Jiang, Wu, and Williams^[32] that stated "Different results can be more useful than blinded applications of only one method, and uninformative answer can be better than misleading one." The norm in CEA methodology is the combination of arithmetic mean, ICER, QALY, and societal perspective. Other methods may be considered in ancillary or sensitivity analyses.

Another less-discussed issue in CEA is related to multiplicity, selective reporting, confounding, and (external) validation which have been extensively discussed in other disciplines (e.g., EA using observational data). For instance, publication bias and selective reporting could be serious concerns; a majority of CEA publications showed ICER < \$50,000/QALY.^[33] Due to the heterogeneity of data sources, the variety of analytic methods/approaches, and the inherent subjectivity in outcomes, exploration rather than definitive conclusion may be a realistic goal.

CONCLUSION

In general, methodologies, implementation, and interpretation of EA, including meta-analysis, are reasonably well established and standardized; thus, the same or well-agreed methods, tests, computing software, and data sets can be used around the world (e.g., FDA, clinical trial course in biostatistics program, and clinical trial guidelines such as <http://www.consort-statement.org/>). In comparison, cost analysis and, to an even greater extent, CEA are destined to be more complicated and nuanced, where a set of recommendations and several guidelines are available (e.g., 1st and 2nd U.S. Panels on Cost-Effectiveness in Health and Medicine; WHO-CHOICE, <http://www.who.int/choice/cost-effectiveness/en/>; and ISPOR's CHEERS).

It is not uncommon to have one or two results for EA but 10 different results for CEA for a single aim/hypothesis. A valid comparative EA alone requires significant time and effort and is generally achieved via a well-done RCT, which is launched after sufficient cumulative evidence/justification. Its CEA counterpart would require even more time and work.

It is important to recognize that CEA can aid decision-making but does not make the decision for us. Other issues that must be considered are burden of disease, degree of uncertainty, CEA or unavailability of cost data, value judgement, non-economic or non-medical reasons for adoption or switching, monopoly prevention, and political price of saying “no” to some patients or treatments. Many health policy decisions are complex and controversial processes. Transparency in CEA would be essential, including data and model/algorithm sharing. The realistically best strategy may be to plan CEA alongside EA whenever feasible; beyond that, CEA follow-up that integrates more evidence and data can be conducted or awaited.

Covariate-Adjusted Adaptive Dose-Finding: Early Phase Clinical Trials

Peter F. Thall and Hoang Q. Nguyen

Department of Biostatistics, The University of Texas, M.D. Anderson Cancer Center, Houston, Texas, U.S.A.

Abstract

Most methods for sequentially adaptive dose-finding in phase I clinical trials characterize outcome as an indicator Y_T of toxicity and assume that patients are homogeneous. This entry reviews a new method which requires an informative prior on covariate effect parameters, obtained from historical data.

Keywords: Adaptive design; Bayesian design; Individualized treatment; Phase I clinical trial; Phase I/II clinical trial.

INTRODUCTION

Most methods for sequentially adaptive dose-finding in phase I clinical trials characterize outcome as an indicator Y_T of toxicity and assume that patients are homogeneous. Dose-finding is based on an algorithm involving $(x, Y_T)^{[1,2]}$ or model-based criteria defined in terms of $\pi_T(x, \theta) = \Pr(Y_T = 1 | x, \theta)^{[3,4]}$ where x denotes dose and θ is a model parameter vector. Doses are chosen adaptively for successive patient cohorts, with the main scientific goal to choose a dose having an acceptable probability of toxicity from a set $\mathcal{X} = \{x_1, \dots, x_K\}$. There are two useful extensions of this paradigm. The first accounts for effects of patient covariates, $\mathbf{Z} = (Z_1, \dots, Z_q)$, and so that $\pi_T(x, \theta)$ becomes $\pi_T(x, \mathbf{Z}, \theta)$. This provides a basis for using each patient's $\mathbf{Z}$ to improve dose selection, so-called “patient-specific” or “individualized” dose assignment.^[5-9] The second extension uses an indicator Y_E of efficacy along with Y_T to choose doses, giving a so-called “Phase I/II” design,^[10-18] with the aim to choose an x having acceptably large $\pi_E(x)$ and small $\pi_T(x)$.

We review a new method^[19] that combines these two extensions by basing dose-finding on $\mathbf{Y} = (Y_E, Y_T)$ while also accounting for $\mathbf{Z}$. For $k = E, T$ let $\pi_k(x, \mathbf{Z}, \theta) = \Pr(Y_k = 1 | x, \mathbf{Z}, \theta)$ for a patient with covariates $\mathbf{Z}$ treated with dose x , with $\pi(x, \mathbf{Z}, \theta) = (\pi_E(x, \mathbf{Z}, \theta), \pi_T(x, \mathbf{Z}, \theta))$, denoted respectively by π_E, π_T and π for brevity. The method requires an informative prior on covariate effect parameters, obtained from historical data. Elicited lower limits on π_E and upper limits on π_T for each of a representative set of covariate vectors are used to construct bounding functions that determine the acceptability of each element of $\mathcal{X}$ for each $\mathbf{Z}$. For a reference vector $\mathbf{Z}^*$, the physician must specify several equally desirable target values of π

that are used to construct criteria for comparing acceptable doses. Rather than choosing one best dose, the data from the trial are used to select $\mathbf{Z}$ -specific x for future patients.

PROBABILITY MODEL

Regression Models for Efficacy and Toxicity

Let $D_n = \{(\mathbf{Y}_i, \mathbf{Z}_i, x_{[i]}), i = 1, \dots, n\}$ denote the data from the trial's first n patients where $x_{[i]}$ is the dose of patient i , and denote the historical data by $\mathcal{H} = \{(\mathbf{Y}_i, \mathbf{Z}_i, \mathcal{T}_{[i]}), i = 1, \dots, n_H\}$, where $\{\mathcal{T}_1, \dots, \mathcal{T}_m\}$ are the historical treatments and $\mathcal{T}_{[i]}$ is the i th patient's treatment. Let unsubscripted T denote either a dose or historical treatment. For a patient with covariates $\mathbf{Z}$ treated with T let $\pi_{a,b}(T, \mathbf{Z}, \theta) = \Pr(Y_E = a, Y_T = b | T, \mathbf{Z}, \theta)$, for $a, b \in \{0, 1\}$ so that $\pi_E(T, \mathbf{Z}, \theta) = \Pr(Y_E = 1 | T, \mathbf{Z}, \theta) = \pi_{1,1}(T, \mathbf{Z}, \theta) + \pi_{1,0}(T, \mathbf{Z}, \theta)$ and $\pi_T(T, \mathbf{Z}, \theta) = \Pr(Y_T = 1 | T, \mathbf{Z}, \theta) = \pi_{1,1}(T, \mathbf{Z}, \theta) + \pi_{0,1}(T, \mathbf{Z}, \theta)$. For link function g , denote the linear terms $\eta_k = g(\pi_k)$. The bivariate model is determined by the marginals $\pi_E = g^{-1}(\eta_E)$ and $\pi_T = g^{-1}(\eta_T)$ and one association parameter, ψ . There are many possible models, including the Gumbel

$$\pi_{a,b} = \pi_E^a (1 - \pi_E)^{1-a} \pi_T^b (1 - \pi_T)^{1-b} + (-1)^{a+b} \psi \pi_E^a (1 - \pi_E)^{1-a} \pi_T^b (1 - \pi_T)^{1-b}, \quad (1)$$

with $-1 \leq \psi \leq 1$, and bivariate copulas,^[20] including the Gaussian copula

$$C_\psi(u, v) = \Phi_\psi(\Phi^{-1}(u), \Phi^{-1}(v)), \quad 0 \leq u, v \leq 1, \quad (2)$$

where Φ is the $N(0, 1)$ cdf and Φ_ψ is the bivariate $N(0, 1)$ cdf with correlation ψ . This gives $\pi_{0,0} = \Phi_\psi(\Phi^{-1}(1 - \pi_E), \Phi^{-1}(1 - \pi_T))$, $\pi_{1,0} = 1 - \pi_T - \pi_{0,0}$, $\pi_{0,1} = 1 - \pi_E - \pi_{0,0}$ and $\pi_{1,1} = \pi_E + \pi_T + \pi_{0,0} - 1$.

Given a bivariate model, the following forms of $\eta_E(T, \mathbf{Z}, \theta)$ and $\eta_T(T, \mathbf{Z}, \theta)$ provide a basis for using H to learn about covariate effects and accounting for joint effects of $(x, \mathbf{Z})$ on π based on the current trial data, D_n . The general form is

$$\eta_k(\mathcal{T}, \mathbf{Z}, \theta) = \beta_k \mathbf{Z} + \sum_{j=1}^m (\mu_{k,j} + \xi_{k,j} \mathbf{Z}) \mathbf{1}(\mathcal{T} = \mathcal{T}_j) + \{\phi_k(x, \alpha_k) + \gamma_k \mathbf{Z}\} \mathbf{1}(\mathcal{T} = x), \quad (3)$$

for $k = E, T$, where $\mathbf{1}(A)$ indicates the event A , and $\phi_E(x, \alpha_E)$ and $\phi_T(x, \alpha_T)$ characterize the main dose effects on π_E and π_T . For each k , the covariate main effects are $\beta_k = (\beta_{k,1}, \dots, \beta_{k,q})$, interactions between $\mathbf{Z}$ and historical treatment T_j are $\xi_{k,j} = (\xi_{k,j,1}, \dots, \xi_{k,j,q})$ and dose-covariate $(x - \mathbf{Z})$ interactions are $\gamma_k = (\gamma_{k,1}, \dots, \gamma_{k,q})$. For $\mathcal{H}$, the expression (3) is

$$\eta_k(T_j, \mathbf{Z}, \theta) = \mu_{k,j} + \beta_k \mathbf{Z} + \xi_{k,j} \mathbf{Z}, \quad (4)$$

for $j = 1, \dots, m$ and $k = E, T$,

where $\mu_k = (\mu_{k,1}, \dots, \mu_{k,m})$ are historical treatment main effects. For the trial, (3) is

$$\eta_k(x, \mathbf{Z}, \theta) = \phi_k(x, \alpha_k) + \beta_k \mathbf{Z} + x \gamma_k \mathbf{Z}, \quad \text{for } k = E, T. \quad (5)$$

The functions ϕ_E and ϕ_T should reflect the application. For example, for a cytotoxic agent, $\phi_T(x, \alpha_T) = \alpha_{T,0} + \alpha_{T,1} x$ with $\Pr(\alpha_{T,1} > 0) = 1$ gives $\pi_T(x, \mathbf{Z}, \theta)$ increasing in x , while a quadratic function $\phi_k(x, \alpha_k) = \alpha_{k,0} + \alpha_{k,1} x + \alpha_{k,2} x^2$ allows π_k to be non-monotone in x , which may be appropriate for biologic agents.

Denote $\alpha = (\alpha_E, \alpha_T)$, $\mu = (\mu_E, \mu_T)$, $\beta = (\beta_E, \beta_T)$, $\gamma = (\gamma_E, \gamma_T)$ and $\xi = (\xi_{E,1}, \xi_{T,1}, \dots, \xi_{E,k}, \xi_{T,k})$ so that $\theta = (\mu, \beta, \xi, \gamma, \alpha, \gamma)$. The likelihood for the current trial data is

$$L(D_n | \theta) = \prod_{i=1}^n \prod_{a=0}^1 \prod_{b=0}^1 \{\pi_{a,b}(x_{[i]}, \mathbf{Z}_i, \theta)\}^{\mathbf{1}\{\mathbf{Y}_i=(a,b)\}}.$$

Denoting $D_n^{\mathcal{H}} = \mathcal{H} \cup D_n$, the posterior is

$$p(\alpha, \gamma, \beta, \psi | D_n^{\mathcal{H}}) \propto L(D_n | \theta) p(\alpha, \gamma) p(\beta, \psi | \mathcal{H}). \quad (6)$$

Prior Specification

A fit of H yields the informative posterior $p = (\mu, \beta, \xi, \gamma | \mathcal{H})$. For covariate-adjusted dose-finding, the informative marginal posterior $p = (\beta, \psi | \mathcal{H})$ is essential, since it is used

as the prior on (β, ψ) at the start of the trial. Because α and γ account for effects of the experimental agent, their priors are non-informative. For prior means, set $E(\gamma) = 0$, and obtain prior $E(\alpha)$, by eliciting means of $\pi_E(x_j, \mathbf{Z}^*, \theta)$ and $\pi_T(x_j, \mathbf{Z}^*, \theta)$ at two or more values of x_j and solving for $E(\alpha)$, using the least squares method of Thall and Cook^[15] if the number of elicited means is larger than $\dim(\alpha)$.

To determine prior variances, assume all entries of α and γ have prior variance σ_0^2 , and calibrate σ_0^2 to control the effective sample size (ESS) of the prior $p\{\pi_k(x_j, \mathbf{Z}^*, \theta)\}$ for all $k = E, T$ and x_j . One may do this by matching the first two moments of each $\pi_k(x_j, \mathbf{Z}^*, \theta)$ with a beta $(a_{k,j}, b_{k,j})$ and approximating the ESS of $p\{\pi_k(x_j, \mathbf{Z}^*, \theta)\}$ by $a_{k,j} + b_{k,j} = E\{\pi_k(x_j, \mathbf{Z}^*, \theta)\} [1 - E\{\pi_k(x_j, \mathbf{Z}^*, \theta)\}] / \text{var}\{\pi_k(x_j, \mathbf{Z}^*, \theta)\} - 1$. A more general definition of ESS is given by Morita, Thall, and Mueller.^[21] To obtain a non-informative prior on dose effects and allow $p = (\beta, \psi | \mathcal{H})$ and the trial's data to dominate the dose-finding decisions, specify σ_0^2 to ensure that all $a_{k,j} + b_{k,j}$ are reasonably small. One also must control $\sigma^2(\alpha_{k,2} x^2) = \text{var}(\alpha_{k,2} x^2)$ relative to $\sigma^2(\alpha_{k,1} x) = \text{var}(\alpha_{k,1} x)$ for each k to avoid the quadratic effect $\alpha_{k,2} x^2$ being too large relative to the first order effect $\alpha_{k,1} x$ and thus misrepresenting ϕ_k . To do this, fix $\sigma(\alpha_{k,1}) = \sigma_0$, and examine effects of the ratio $\sigma(\alpha_{k,2} x^2) / \sigma(\alpha_{k,1} x) = x \sigma(\alpha_{k,2}) / \sigma(\alpha_{k,1}) = x \sigma(\alpha_{k,2}) / \sigma_0$ in the range 0.1 to 1.0 on the design's operating characteristics (OCs), and choose $\sigma(\alpha_{k,2})$ to ensure good OCs and reasonable prior ESS.

COVARIATE-ADJUSTED DOSE-FINDING

At any interim point in the trial, quantities computed from the posteriors $p(\alpha, \gamma, \beta, \psi | D_n^{\mathcal{H}})$ are used to choose doses adaptively. To account for both x and $\mathbf{Z}$, two different criteria are used, the first to determine whether x is *acceptable* for given $\mathbf{Z}$, and the second to quantify the *desirability* of each π in terms of a tradeoff between π_E and π_T .

Dose Acceptability

The following construction obtains a lower bound on $\pi_E(x, \mathbf{Z}, \theta)$ and an upper bound on $\pi_T(x, \mathbf{Z}, \theta)$ as $\mathbf{Z}$ is varied. To begin, a representative set of covariates, $\{\mathbf{Z}^{(1)}, \dots, \mathbf{Z}^{(K)}\}$, must be specified. For each $\mathbf{Z}^{(j)}$, elicit the smallest probability of efficacy, $\underline{\pi}_E^{(j)}$, and the largest probability of toxicity, $\bar{\pi}_T^{(j)}$, that the physician will allow for a patient with covariates $\mathbf{Z}^{(j)}$. Denote $\zeta_k(\mathbf{Z}) = E(\beta_k \mathbf{Z} | H)$. To construct a bounding function for $\pi_E(x, \mathbf{Z}, \theta)$, treat the K pairs $\{(\zeta_E(\mathbf{Z}^{(j)}), \underline{\pi}_E^{(j)}), j = 1, \dots, K\}$, of estimated linear terms and elicited lower bounds on π_E like regression data and fit a smooth curve with $\zeta_E(\mathbf{Z}^{(j)})$ the predictor and $\underline{\pi}_E^{(j)}$ the outcome. A linear function $\underline{\pi}_E(\zeta_E) = a + b \zeta_E$ or quadratic $\underline{\pi}_E(\zeta_E) = a + b \zeta_E + c \zeta_E^2$ work well. Denoting the regression estimate by $\hat{\pi}_E(\zeta_E)$, the *efficacy lower bounding function*

Fig. 1 Dose acceptability bounding functions. Each box represents a pair $(\zeta_E(\mathbf{Z}^{(j)}), \pi_E^{(j)})$ in (a) and a pair $(\zeta_T(\mathbf{Z}^{(j)}), \pi_T^{(j)})$ in (b). An open diamond denotes bounds for a 58-year-old patient with poor cytogenetics, and an open circle denotes bounds for a 48-year-old patient with intermediate cytogenetics

is $\pi_E(\mathbf{Z}) = \hat{\pi}_E \circ \zeta_E(\mathbf{Z})$. Similarly, fit a curve to the K pairs $\{(\zeta_T(\mathbf{Z}^{(j)}), \pi_T^{(j)}), j=1, \dots, K\}$, obtain an estimate $\hat{\pi}_T(\zeta_T)$, and define the *toxicity upper bounding function* to be $\bar{\pi}_T(\mathbf{Z}) = \hat{\pi}_T \circ \zeta_T(\mathbf{Z})$. These values should be plotted to allow any $\pi_E^{(j)}$ or $\pi_T^{(j)}$ to be adjusted if desired. Fig. 1 gives the scattergrams of elicited values and bounding functions for the illustrative trial. Given D_n , the set of acceptable doses for a patient with covariates $\mathbf{Z}$ is

$$A_n(\mathbf{Z}) = \{x \in \chi : \Pr[\pi_E(x, \mathbf{Z}, \boldsymbol{\theta}) < \bar{\pi}_E(\mathbf{Z}) \mid D_n^{\mathcal{H}}] < p_E \text{ and } \Pr[\pi_T(x, \mathbf{Z}, \boldsymbol{\theta}) > \bar{\pi}_T(\mathbf{Z}) \mid D_n^{\mathcal{H}}] < p_T\} \quad (7)$$

The cutoffs p_T and p_E should be calibrated to obtain good OCs, with values around 0.90 to 0.95 generally giving good designs. The set $A_n(\mathbf{Z})$ changes adaptively during the trial for each $\mathbf{Z}$. If $A_n(\mathbf{Z})$ is empty then no dose is acceptable for that patient. If $A_n(\mathbf{Z})$ consists of a single dose then that dose is used by default. If $|A_n(\mathbf{Z})| \geq 2$ then a criterion for choosing the patient's dose from $A_n(\mathbf{Z})$ is needed.

Dose Desirability

To select one dose from $A_n(\mathbf{Z})$, the following criteria for comparing doses may be used. These are defined in terms of a *target contour*, C , of π values that characterizes the tradeoff between π_E and π_T . A general approach for constructing C is to elicit target probability pairs $\pi_1^*, \dots, \pi_c^*$ considered to be equally desirable for a reference patient with covariates $\mathbf{Z}^*$ and define C to be a smooth, strictly increasing curve obtained by treating π_T as a function of π_E and fitting the elicited points. Fig. 2 gives the elicited

values and C in the illustration. An exact method for defining C based on three elicited targets is given by Thall and Cook.^[17]

Given C , the desirability $\delta_n(x, \mathbf{Z})$ of a dose x for a patient with covariates $\mathbf{Z}$ may be defined in several ways. For example, one may define $\delta_n(x, \mathbf{Z})$ to be the posterior probability given $D_n^{\mathcal{H}}$ of the set $\{\pi : \pi_E \geq \pi_E' \text{ and } \pi_T \leq \pi_T', \exists \pi' \in C\}$ of $\pi(x, \mathbf{Z})$ that are at

Fig. 2 Elicited targets and tradeoff contour. The four equally desirable elicited π pairs are denoted by shaded circles located along the fitted contour C . The two dashed line segments illustrate that the π pair (0.50, 0.60), which has desirability 0.24, is preferred over the pair (0.15, 0.45), which has desirability 0.18

least as desirable as a pair on C . Here, we use the following geometric definition based on the point π_c where the straight line segment L_π through π and the ideal point $(1,0)$ intersects C , as shown in Fig. 2. Denoting Euclidean distance by $\|\cdot\|$, the desirability of $\pi \in [0,1]^2$ is defined as $d_c(\pi) = \exp(-\|\pi - (1,0)\| / \|\pi_c - (1,0)\|)$. This function may be used to compare π pairs since $d_c(\pi)$ decreases from its maximum $d_c(1,0) = 1$ as π moves away from the ideal pair $(1,0)$ along any line L_π . Given d , the set of π having $d_c(\pi) = d$ form an *isocontour*, or *indifference* set in $[0,1]^2$. For a patient with covariates $\mathbf{Z}$, the desirability of x is $\delta_n(x, \mathbf{Z}) = d_c(E\{\pi(x, \mathbf{Z}, \theta) | D_n^H\})$, and the best acceptable dose is the x maximizing $\delta_n(x, \mathbf{Z})$.

TRIAL CONDUCT

Designing a trial using this methodology requires one to first analyze available historical data, which is used as a basis for choosing a model among several candidates^[19] and computing $p(\beta, \psi | \mathcal{H})$ under the selected model. One then must establish priors on α and δ doses χ , maximum sample size, N , a set of representative $\mathbf{Z}$, and acceptability and desirability criteria. During the trial, for each new patient $A_n(\mathbf{Z})$ is computed based on that patient's $\mathbf{Z}$ and the current $p(\theta | D_n^H)$, and the following decision rules are applied.

1. If $A_n(\mathbf{Z})$ is empty, do not treat the patient with any $x \in \chi$.
2. If $A_n(\mathbf{Z})$ is not empty, treat the patient using the dose x maximizing $\delta_n(x, \mathbf{Z})$.
3. If $A_n(\mathbf{Z}^{(j)})$ is empty for all $j = 1, \dots, K$, then stop the trial and declare the new agent unacceptable for any patient at any dose.
4. After the trial is completed, select doses for future patients using the acceptability and desirability criteria based on $p(\theta | D_n^H)$.

Rule (1) is a covariate-specific combined futility and safety stopping rule. This provides a formal basis for decisions based on a patient's particular characteristics that typically must be made subjectively by the physician when a design that ignores covariates is used.

ILLUSTRATION

Our illustration is a phase I/II trial of a chemo-protective agent (CPA), given at one of five dose levels 12, 15, 18, 21, or 24 mg/m² daily for three days, combined with fixed doses of the standard drugs idarubicin (IDA) and cytosine arabinoside in untreated acute myelogenous leukemia (AML) patients under age 60. The therapeutic goal of chemotherapy for AML is to achieve complete remission (CR), defined as recovery of circulating blood cells and immature cells in the bone marrow to normal levels. For the trial, E is the event that the patient is alive and in CR at day 42 of treatment, and T is defined as severe mucositis, diarrhea, pneumonia, or sepsis within 42 days. The design was motivated by the problem that higher doses of IDA increase both π_E and π_T , and the hypothesis that the CPA would decrease the risk of IDA-induced toxicity. Additional details are given in Thall, Nguyen, and Estey.^[19]

The covariates used in the design were Age, with $Z_1 = .01(\text{Age} - 45)$ for numerical stability, and cytogenetic abnormality (Cyto), classified in terms of prognosis as Good, Intermediate or Poor, with $Z_2 = 1$ (Cyto = Good) and $Z_3 = 1$ (Cyto = Poor). Quadratic dose effects $f_k(x, \alpha_k) = \alpha_{k,0} + \alpha_{k,1}x + \alpha_{k,2}x^2$ for both $k = E$ and T were assumed, with dose levels coded as $x = -2, -1, 0, 1, 2$. Analyses of historical data from 693 untreated AML patients age <60 treated with chemotherapy showed that, among a set of models defined in terms of bivariate distributional form and link function, the Gaussian copula with probit link gave the best fit to H . Table 1 gives posterior means and standard deviations of $\pi_E(\mathbf{Z}, \theta)$ and $\pi_T(\mathbf{Z}, \theta)$ under

Table 1 For Each Representative $\mathbf{Z}$, Posterior Means of $\pi(\mathbf{Z}, \theta)$ under the Gaussian Copula with Probit Link and Desirabilities Based on the Historical Data and Corresponding Elicited Bounds on $\pi_E(\mathbf{Z}, \theta)$ and $\pi_T(\mathbf{Z}, \theta)$

this model for each $\mathbf{Z}$ in the representative set of nine covariate vectors. The posterior mean historical covariate effects were $\zeta_E(\mathbf{Z}) = 0.262 - 1.308Z_1 + 0.818Z_2 - 0.785Z_3$ and $\zeta_T(\mathbf{Z}) = -0.232 + 1.619Z_1 - 0.542Z_2 + 0.148Z_3$. The acceptability bounding functions, derived from the elicited covariate-specific limits given in Table 2, were the quadratic functions

$$\pi_E(\mathbf{Z}) = 0.4063 + 0.4078\zeta_E(\mathbf{Z}) - 0.0806\{\zeta_E(\mathbf{Z})\}^2$$

and

$$\pi_T(\mathbf{Z}) = 0.5890 + 0.4739\zeta_T(\mathbf{Z}) + 0.1403\{\zeta_T(\mathbf{Z})\}^2.$$

These bounding functions are plotted in Fig. 1. The acceptability criteria were applied with $p_E = p_T = 0.90$. The target contour C was obtained by fitting a quadratic to the four target pairs (0.75, 0.50), (0.30, 0), (1, 0.60), (0.40, 0.12), considered equally desirable improvements over the historical mean $E\{\pi(\mathbf{Z}^*, \theta) | \mathcal{H}\} = (.59, .43)$ for a reference patient with $\mathbf{Z}^* = (48, \text{Intermed})$. The fitted target curve was $\pi_T = -.5605 + 2.1226\pi_E - .9591\pi_E^2$, and C was defined

to be the set of π satisfying this equation for $0.30 \leq \pi_E \leq 1$, as shown in Fig. 2.

Elicited prior means of $\pi(x_j, \mathbf{Z}^*, \theta)$ for the five dose levels were the historical means (0.59, 0.43), (0.70, 0.50), (0.75, 0.55), (0.85, 0.70), and (0.90, 0.90), for the doses 12, 15, 18, 21, and 24 mg/m². A least squares fit^[15,19] yielded prior means (0.773, 0.262, 0.0077) for $(\alpha_{E,0}, \alpha_{E,1}, \alpha_{E,2})$ and (0.098, 0.344, 0.1025) for $(\alpha_{T,0}, \alpha_{T,1}, \alpha_{T,2})$. The prior means of all $x - \mathbf{Z}$ interaction parameters γ_E and γ_T were set equal to 0, with a maximum ESS of 1.3 for any $\pi(x_j, \mathbf{Z}^*)$. Each parameter in $\alpha_E, \alpha_T, \gamma_E$ and γ_T was given prior standard deviation 1.33, except for those of the quadratic coefficients $\alpha_{E,2}$ and $\alpha_{T,2}$, which were set equal to 0.266.

The planned maximum sample size of the AML trial was $N = 60$ patients. Fig. 3 illustrates the posteriors of $\pi(x_j, \mathbf{Z}, \theta)$ and corresponding desirability $\delta_n(x_j, \mathbf{Z})$ for each combination of x_j and $\mathbf{Z} = (27, \text{Good}), (48, \text{Interm})$ or $(58, \text{Poor})$ based on the final data D_{60} of a hypothetical trial.

Table 2 summarizes four scenarios under which the trial was simulated. Three methods were studied in the simulations: (i) the covariate-adjusted method as described here including $x - \mathbf{Z}$ interactions, denoted by $\mathbf{Z}$ -INT; (ii) the

Fig. 3 Illustration of the posteriors of $\pi_E(X_j, \mathbf{Z})$ and $\pi_T(X_j, \mathbf{Z})$ corresponding desirability values $\delta(X_j, \mathbf{Z}) = r_c\{\pi(X_j, \mathbf{Z})\}$ for each dose and $\mathbf{Z} = (27, \text{Good})$, $(48, \text{Interm})$ and $(58, \text{Poor})$. In the third column, the desirabilities of acceptable and unacceptable doses are represented by shaded and unshaded rectangles, respectively

covariate-adjusted method assuming that no $x - \mathbf{Z}$ interactions, $\gamma = 0$, denoted by $\mathbf{Z}$ -NO INT; and (iii) the simplified version of the method that ignores covariates entirely, denoted by NO $\mathbf{Z}$. To compare the methods for each $\mathbf{Z}$ under each scenario, the followed statistic was used. Given $\mathbf{Z}$ and D_n , unless $A_n(\mathbf{Z})$ is the empty set, let $x(\mathbf{Z}, D_n)$ denote the covariate-specific dose that is selected. The true value of $\pi(x(\mathbf{Z}, D_n), \mathbf{Z})$ under the scenario and thus $d_c\{\pi(x(\mathbf{Z}, D_n), \mathbf{Z})\}$ at the selected dose for the given $\mathbf{Z}$ are known. A statistic that compares the selected $x(\mathbf{Z}, D_n)$ to

the best possible dose that could have been selected for a patient with covariates $\mathbf{Z}$ is

$$\rho(\mathbf{Z}) = \frac{d_c\{\pi(x(\mathbf{Z}, D_n), \mathbf{Z})\}}{\max_{j=1, \dots, 5} d_c\{\pi(x_j, \mathbf{Z})\}}. \quad (8)$$

This takes on values between 0 and 1, with $\rho(\mathbf{Z}) = 1$ if the best possible dose was selected.

Under Scenario 1, there are no $x - \mathbf{Z}$ interactions ($\gamma = 0$) the desirability $d_c(\pi_E, \pi_T)$ increases with x for each $\mathbf{Z}$,

and for each x the values of $d_c(\pi_E, \pi_T)$ change dramatically with $\mathbf{Z}$. This scenario is similar to what was seen in the historical data. Scenario 2 is obtained from Scenario 1 by adding the $x - \mathbf{Z}$ interactions $\gamma_{E,2} = \gamma_{E,Good} = .6, \gamma_{E,3} = \gamma_{E,Poor} = -.8, \gamma_{T,2} = \gamma_{T,Good} = -.6, \gamma_{T,3} = \gamma_{T,Poor} = .8$. This says that, for higher x , the $x - \mathbf{Z}$ interactions lead to larger $\pi_E(x, \mathbf{Z}, \theta)$ and smaller $\pi_T(x, \mathbf{Z}, \theta)$ for patients with Good Cyto, whereas the $x - \mathbf{Z}$ interactions have the opposite effect on patients with Poor Cyto. These effects are illustrated strikingly by Fig. 4, which shows that higher doses are more desirable for patients with Good or Intermediate Cyto but lower doses are more desirable for patients with Poor Cyto. In Scenario 3, $\pi_T(x, \mathbf{Z}, \theta)$ and $d_c(\pi_E, \pi_T)$ are non-monotone in x , with $d_c(\pi_E, \pi_T)$ largest at the middle

dose. Scenario 4 is obtained from Scenario 3 by adding the same $x - \mathbf{Z}$ interaction parameters as in Scenario 2.

The simulation results are presented graphically in Fig. 5. The $\mathbf{Z}$ -INT method does a very reliable job of selecting the most desirable doses within patient prognostic subgroups. The results for Scenarios 2 and 4 show that the method very reliably detects $x - \mathbf{Z}$ interactions and selects the doses that are most desirable within each subgroup. In contrast, under the $x - \mathbf{Z}$ interaction Scenarios 2 and 4, the $\mathbf{Z}$ -No INT method has ρ values substantially lower than those for $\mathbf{Z}$ -INT, and the ρ values for the No $\mathbf{Z}$ method are extremely low for (58, Poor) patients. Thus, either ignoring $x - \mathbf{Z}$ interactions or ignoring covariates produces a method with greatly inferior properties.

CONCLUSIONS

The phase I/II design described here chooses doses based on efficacy and toxicity while accounting for each patient's prognostic covariates. The method is very complex, and requires a substantial effort from both the statistician and the physicians. Computer simulations show that this complexity is justified, since the method provides substantial improvements over simpler versions that either ignore $x - Z$ interactions or ignore covariates entirely.

Covariates: Adjustment for

Thomas Permutt

U.S. Food and Drug Administration, Rockville, Maryland, U.S.A.

Abstract

The techniques of analysis of covariance are employed in three mathematically similar but conceptually very different kinds of problem. Examples of all three kinds arise in connection with the development of pharmaceutical products. This entry is focused on the adjustment for covariates in an experimental setting.

INTRODUCTION

The techniques of analysis of covariance are employed in three mathematically similar but conceptually very different kinds of problem. Examples of all three kinds arise in connection with the development of pharmaceutical products.

In the first case, a regression model is expected to fit the data well enough to serve as the basis for prediction. In testing the stability of a drug product, for example, the potency may be modeled as a linear function of time, and the possibility of different lines for different batches of the product needs to be allowed for. The purpose of the statistical analysis is to ensure, with a stated degree of confidence, that the potency at a given time will be within given limits.

The second and perhaps widest application of analysis of covariance is in observational studies, such as arise in the postmarketing phase of drug development. It may be desired, for example, to study the association of some outcome with exposure to a drug. It is necessary to adjust for covariates that may be systematically associated both with the outcome and with the exposure and so induce a spurious relationship between the outcome and the exposure. In such studies the unexplained variation is typically high, so the model is not expected to fit the individual observations well. It must, however, include all the important potential confounders and must have at least approximately the right functional form, if a causal relationship, or the absence of one, between the outcome and the exposure is to be inferred.

The third kind of application of analysis of covariance, although the first historically,^[1] is to randomized, controlled experiments such as clinical trials of the efficacy of new drugs. In such experiments, adjustment for covariates is optional in a sense, because the validity of unadjusted

comparisons is ensured by randomization. Adjustments properly planned and executed, however, can reduce the probabilities of inferential errors and so help to control the size, cost, and time of clinical trials.

The modeling problem is straightforward, well covered in textbooks, and, strictly speaking, not a matter of “adjustment.” The observational problem, in contrast, is essentially intractable from the standpoint of formal statistical inference; but heuristic methods have had wide application and discussion. We focus here on the adjustment for covariates in the experimental setting. This problem has had relatively little attention in the literature, partly because early writings^[1] are largely complete, correct, and still sufficient. Unfortunately, the more recent literature on modeling and on observational studies has been misapplied to the experimental problem. Either a well-fitting model is thought to be required, as in the first problem, or the analysis is supposed to be heuristic, as in the second. In fact, a rigorous theory of analysis of covariance in controlled experiments can be developed, even in the absence of a good model for the covariate effects.

ADJUSTING FOR BASELINE VALUES

Consider the case of a randomized trial of two treatments, with a continuous measure of outcome (Y) that is also measured at baseline (X). If the populations are normal or the samples are large, the treatments might be compared by a two-sample t -test on the difference in mean outcome $\bar{Y}$. Alternatively, the change from baseline, $Y-X$, might be analyzed in the same way. The difference between groups in $\bar{Y}$ and the difference between groups in $\bar{Y}-X$ have the same expectation, because the expected difference between groups in $\bar{X}$ is zero. We therefore have two unbiased estimators of the same parameter. They have different variances, according to how well the baseline predicts the outcome. If the variances (within treatment groups) of baseline and outcome

The opinions expressed are those of the author and not necessarily of the U.S. Food and Drug Administration.

are the same and the correlation is ρ , then the standard errors are in the ratio $(2 - 2\rho)^{1/2}$. The adjusted estimator is better if $\rho > 0.5$.

Of course, there is no need to choose. The average of the two estimators has standard error proportional to $(1.25 - \rho)^{1/2}$, which is less than either of the two whenever $0.25 < \rho < 0.75$. This average can be written as the difference between treatment groups in $\bar{Y} - 0.5\bar{X}$. So $\bar{Y} - 0.5\bar{X}$ is a less variable measure of outcome than either the mean raw score $\bar{Y}$ or the mean difference from baseline $\bar{Y} - \bar{X}$, whenever the correlation is between 0.25 and 0.75. This can, but need not, be viewed as fitting parallel straight lines with slope 0.5 to the two groups and measuring the vertical distance between them.

Naturally, there is no need to choose 0.5 either. The difference in group means of any statistic of the form $Y - \beta X$ can be used to estimate the treatment effect. The smallest variance, and so the most sensitive test, is achieved when β happens to coincide with the least-squares common slope, but the variance does not increase steeply as β moves away from this optimal value. Thus, even a very rough a priori guess for β is likely to perform better than either of the special cases $\beta = 0$ (no adjustment) and $\beta = 1$ (subtract the baseline).

Finally, there is no need to guess. The least-squares slope, calculated from the data, can be used for β , without any consequences beyond the loss of a degree of freedom for error. Asymptotic theory for the resulting adjusted estimator of the treatment effect was given by Robinson,^[2] and an exact, small-sample theory by Tukey.^[3]

In general, then, the best way to adjust for a baseline value is neither to ignore it nor to subtract it, but to subtract a fraction of it. The fraction will be estimated from the data, simultaneously with the treatment effect, by analysis of covariance. There is no need to check the “assumption” that the outcome is linearly related to the baseline value, because this assumption plays no role in the analysis. If it did, not only the analysis of covariance would be tainted: After all, the unadjusted analysis also “assumes” a linear relationship, with slope 0, and the change-from-baseline analysis “assumes” a slope of 1.

OTHER COVARIATES

Any single, prespecified covariate can be adjusted for in much the same way as a baseline measurement of the outcome variable. That is, the mean of a linear function $Y - \beta X$ may be compared across treatment groups, the coefficient β being estimated, simultaneously with the treatment effect, by least squares. Again, the much-tested assumption of a linear relationship between Y and X is superfluous. Two other critical assumptions are sometimes neglected, however.

First, the covariate must be unaffected by treatment. While it is possible to give an interpretation of analysis of covariance adjusting for intermediate causes, this interpretation is not often useful in clinical trials. Any covariate measured before randomization is acceptable. With care, some covariates measured later may be assumed to be unaffected by treatment: the weather, for example, in a study of seasonal allergies. It may be noted that, while analysis of covariance is not usually appropriate for variables in the causal pathway, some of the advantages of analysis of covariance are shared by instrumental-variables techniques^[4] that are appropriate.

Second, the covariate is assumed to be prespecified. Model-searching procedures are unavoidable in observational studies, for there are typically many potential confounding variables whose effects must be considered and eliminated if necessary. Alarming little is known about the statistical properties of such procedures, however, and what is known is not generally encouraging. It is usual, although unjustifiable, to ignore the searching process in reporting the results, presenting simply the chosen model, its estimates, and its optimistic estimates of variability.

Randomized trials are radically different from observational studies in this respect. There is no confounding, because a covariate cannot be systematically associated with treatment if it is not affected by treatment and if treatment is assigned at random. The purpose of analysis of covariance in randomized studies is to reduce the random variability of the estimated treatment effects by eliminating some of what would otherwise be unexplained variance in the observations. This difference has implications for the choice of covariates, which will be discussed in the next section.

CHOICE OF COVARIATES

Whereas a confounder in an observational study is a variable correlated both with the outcome and with the treatment, a useful covariate in a randomized trial is a variable correlated just with the outcome. The greater the absolute correlation, the more the reduction in residual variance and so also in the standard error of the estimated treatment effect. This benefit is realized whether the treatment groups happen to be balanced with respect to the covariate or not. It is neither necessary nor useful, therefore, to choose covariates retrospectively, on the basis of imbalance.^[5]

It is accordingly safe to prespecify, in the protocol for a randomized trial, a covariate, or a few covariates, unaffected by treatment but likely to be correlated with the outcome. Analysis of covariance, adjusting for these covariates, may then be carried out and relied on, without

any justification after the fact. The probability of type I error will be controlled by significance testing, and the probability of type II error will be less than if covariates were not used.

The improvement, however, depends on the correlations (and partial correlations) between the covariates and the outcome, and these may not be perfectly known ahead of time. It might therefore seem advantageous to determine the correlations for some candidate covariates with the data in view, and select a subset that explains a high proportion of the variance of the outcome. With care, it is possible to specify an unambiguous algorithm for selecting a model and to control the probability of type I error.^[3] It is not known, however, whether such procedures have any advantage with respect to type II error over simply prespecifying the model. In practice, in critical efficacy trials the relevant covariates will often be apparent in advance; and when they are not, it may not be any easier or better to specify a set of candidates and an algorithm for choosing among them than to specify a single model.

The properties of models with large numbers of covariates are not well understood. Various rules of thumb relating the number of variables to the sample sizes have been given, but none has any compelling theoretical justification. Furthermore, searches in large sets of potential models probably share some of the defects of models with many covariates, even if the chosen model has only a few covariates.

NONLINEAR MODELS

The word *linear* in the context of the analysis of covariance may be understood in two senses. In many applications, the model is linear in the covariates. However, a model with polynomial or other nonlinear covariate effects is still linear in the *coefficients*, and the least-squares estimators are consequently linear functions of the outcome measurements, so the theory of the general linear model applies. In contrast, logistic, proportional-hazards, and Poisson regression models all involve covariates in a more fundamentally nonlinear way.

Nonlinear covariate effects can be added to an analysis of covariance without difficulty. The most common examples are the 1/0 variables used to represent categorical covariates, but polynomial, logarithmic, exponential, and other functions may sometimes be useful. It is important to bear in mind, however, that in randomized trials the purpose of the covariate model is to reduce unexplained variance. Thus, nonlinear terms should be introduced when they are expected to explain substantial variance in the outcome, and not simply because it is feared that the “assumption” of a linear relationship between the outcome and the covariate may be violated.

Conversely, trials with outcomes that are successes or failures, survival times, or small numbers of events are analyzed by methods that are nonlinear in the second sense. Recent theoretical developments (the generalized linear model) and computer programs have tended to emphasize the analogies between these methods and the linear model. Some of the same principles undoubtedly apply when such methods are used to analyze randomized trials. For example, if a model selection procedure is used, it is vital to understand the statistical properties of the procedure as a whole, rather than simply to report the nominal standard errors and *p*-values of the model that happens to be chosen. On the other hand, the similarity in form may conceal important differences in mathematical structure between linear and nonlinear models, and the linear results must not be casually assumed to have nonlinear analogs. It is not clear, for example, that the robustness of linear models against misspecification in randomized trials carries over to all the nonlinear cases.

INTERACTION

If the difference in mean outcome between treatments changes as a covariate changes, there is said to be a treatment-by-covariate interaction. In a drug trial, such a finding would have important implications. In the extreme case, the treatment effect might change direction as the covariate changed. That is, a drug that was beneficial in one subset of patients, identified by the covariate, would be harmful in a different subset. Clearly such a drug would be “effective.” Equally clearly, for such a drug to be useful, the populations in which it was beneficial and harmful would need to be characterized. In less extreme cases, where the magnitude but not the direction of the treatment effect changes, considerations of risk and benefit might also make it very desirable to estimate the effect in different subgroups.

The question of interaction often arises in connection with analysis of covariance, but it really has little to do with adjustment for covariates. Everything in the preceding paragraph is equally true whether the covariate in question is adjusted for, ignored, or even unmeasured. Furthermore, if the treatment main effect is to be estimated, it is still better to estimate it by analysis of covariance, even without an interaction term, than by the unadjusted difference in means. As with the “assumption” of linearity, the analysis of covariance is not invalidated by violation of the “assumption” of parallelism, for this assumption plays no role in the analysis. Also, as with linearity, if this assumption were crucial, its failure would taint as well the unadjusted analysis, which also “assumes” parallel regressions of the outcome on the covariate, but forces them to have slope 0.

The possibility of interaction should be taken into account whenever it appears at all probable that different groups may respond differently. The reason for this is practical and concerns the interpretation and application of the results of a successful trial. However, the presence of interaction or, what is more common, the inability to rule interaction in or out with confidence, should not be seen as invalidating analysis of covariance nor, especially, as a reason to prefer unadjusted analysis.

Crossover Design

Stephen Senn

Department of Statistics, University of Glasgow, Glasgow, U.K.

Abstract

Crossover trials are potentially extremely efficient designs for studying the effects of treatment. The focus of this entry is on the types of projects for which crossover design is an efficient method.

Keywords: Carryover; Crossover; Placebo-controlled trial.

INTRODUCTION

“A cross-over trial is one in which individual subjects are given sequences of treatments with the object of studying differences between individual treatments (or subsequences of treatments).”^[1]

Crossover trials are potentially extremely efficient designs for studying the effects of treatment. They are, however, not suitable for all disease indications and they can be affected by carryover, a phenomenon that may make it impossible to produce unbiased estimates except by sacrificing the efficiency crossover designs are employed to provide. This important issue will be dealt with extensively below. First, however, some general features of such trials, and possible uses, will be reviewed.

OVERVIEW

The most studied form of crossover is the so-called AB/BA crossover in which patients are treated in two periods and are randomized to receive either treatment A followed by treatment B or vice versa.

Example 1. A trial was carried out to compare the effects in Swedish schoolchildren suffering from asthma of a single dose of 200 μg salbutamol and 12 μg formoterol, both given by metered-dose inhaler.^[2] Fourteen children were randomized in equal numbers to one of two sequences: either formoterol followed by salbutamol or salbutamol followed by formoterol. A washout period of at least 2 days was observed between treatments. The principal outcome measure was peak expiratory flow in 1 second (PEF).^[1]

More complicated crossover designs are often used, however, and designs in which patients receive three, four, or five treatments in as many periods are not uncommon.

Example 2. A placebo-controlled trial in migraine was run in Sweden and Finland to estimate and compare the effects of two doses (50 and 100 mg) of the potassium salt of diclofenac.^[3] Each of 72 patients received each treatment

once and once only. Patients were randomized to receive one of the six possible sequences of the three treatments. Patients were not to use the first treatment until they had observed a treatment-free and attack-free period of at least 1 week. Thereafter they were to treat the first three attacks with the treatments provided in the order indicated. The main outcome measure was a visual analogue pain score two hours after treatment.^[1]

Crossover trials are of greater importance for the biopharmaceutical statistician than is generally the case for fellow medical statisticians working outside of the industry. Some typical applications in drug development are:

- Phase I
 - Pharmacokinetic studies to establish concentration time profiles.
 - Bioequivalence.^[4]
 - Food interaction studies.
 - Dose proportionality.
 - Dose-escalation studies for investigating maximum tolerated dose.
- Phase II
 - Studies of pharmacodynamic response.
 - Dose finding.
 - Parallel assay.
- Phase III
 - Specialist scientific studies.
 - Determination of individual response.
- Phase IV
 - Studies of patient preferences.

Example 3. This is an example of a pharmacodynamic parallel assay in asthma.^[5] Three single doses (6, 12, and 24 μg) for each of two formulations of formoterol to be given by inhalation in the form of a dry powder were compared to placebo. It was not possible to treat patients in more than five periods. Hence, an incomplete blocks design in five periods and 21 sequences was chosen, each patient receiving five of the seven treatments. The trial was

carried out in 15 centers in four countries and 161 patients were recruited. The main outcome variable was the area under the forced expiratory volume in 1 second (FEV₁) curve over 12 hours.

Crossover trials are also used in preclinical work involving animals. This topic is not covered here. Crossover trials are rarely used as pivotal phase III studies in support of a drug application. One reason is that drug regulatory agencies are wary of crossover trials because of the potential danger of carryover. This issue is dealt with in detail in the section “Carryover.” An even more important reason is that a principle advantage of crossover trials is to reduce the number of patients in a trial. However, for most drug developments, more patients are needed to satisfy the regulator as regards the tolerability of the product than are needed to demonstrate its efficacy, even if a parallel group trial is chosen. There is thus less incentive for the sponsor to use crossover trials in phase III. The exception as regards sample size requirements would be trials in which survival is the outcome, but these are, of course, in any case not suitably run as crossovers nor, indeed, are any trials in which cure or death is the outcome.

In fact, suitable indications for crossovers are chronic diseases in which the patients are relatively stable. Such indications include asthma, mild or moderate hypertension, rheumatism, migraine, sleep disturbances, angina, and epilepsy.

It is not the disease alone, however, that determines the suitability of a crossover. Also relevant is the nature of the treatment. Quickly reversible treatments are more suitable than those for which the effect is more persistent. Thus, for example, in asthma, beta-agonists are easier to study using crossover trials than are steroids. Other considerations also apply. An important distinction in drug development is between single-dose studies, which often involve pharmacodynamic measures and may study onset and duration of action, and multidose studies in which, more usually, the therapeutic steady-state effect of treatments is studied. Crossover trials may be used for both but are generally more suited to the former.

CARRYOVER

The outstanding problem of crossover trials is regarded by many as being carryover. Carryover has been defined as, “the persistence (whether physically or in terms of effect) of a treatment applied in one period in a subsequent period of treatment” (Ref. [1]). The simplest example of carryover is where the half-life of a treatment has been underestimated and some relevant concentration of the previous treatment is still present at a time when another is being measured. However, except for bioequivalence studies in which drug concentration itself is the outcome, it is the pharmacodynamic time course rather than the pharmacokinetic course that is relevant. Much play has also been

made in the literature of so-called psychological carryover, where perhaps some memory of the therapeutic experience under the previous treatment affects the patient’s current judgement. However, it should not be forgotten that in a double-blind trial, to the extent that blinding is successful, the origin of all carryover, however indirectly, must ultimately be pharmacological.

Where it occurs, the consequence of carryover is that the trialist will measure the combined (in some cases partial) effects of two or more treatments. (S)he may be unaware that this is happening and this may lead to biased assessment and even where detected the disentangling of individual effects may be difficult. The most appropriate way to deal with carryover is with washout periods. These may be “passive” in that no treatment is given or “active.” The latter strategy occurs quite commonly in multidose therapeutic trials. Here patients may be switched over almost immediately to the subsequent treatment. The previous treatment will, of course, be being eliminated by the patient’s body during the time that the new treatment is being given. Provided measurement of the effects of the new treatment is delayed until this process is complete, the problem of carryover is dealt with.

If, however, as is sometimes the case in single-dose pharmacodynamic studies, it is desired to study onset of action, then a passive washout is necessary. The issue of modeling carryover is considered in due course below.

ANALYSIS USING THE GENERAL LINEAR MODEL

In many cases the primary outcomes for a crossover trial will be continuous. For example, FEV₁ is commonly used in asthma and diastolic or systolic blood pressure in hypertension. As explained above, crossover trials are often more relevant to studying pharmacodynamic rather than therapeutic outcomes. In particular, except in rare cases to be discussed below, survival is not a relevant outcome for a crossover trial. A general linear model in which disturbance terms are assumed to be normally distributed will often be a suitable framework for analysis.

Crossover trials share a feature of fractional factorials that can make their representation in a linear model somewhat awkward. Consider an AB/BA crossover trial in two patients only. There are two patients, two periods, and two treatments but only four and not eight observations. A consequence of this is that two of the three factors patient, period, and treatment determine the third. Thus, if patient 1 is allocated to the AB sequence if the current observation is the observation in period 2, it must be under treatment B.

If we ignore the problem of carryover, then, following Jones and Kenward,^[6] a general model for observed values y_{ijk} of a random variable Y_{ijk} from a crossover trial in g sequences, p periods, N patients, and t treatments is given as follows

$$Y_{ijk} = \mu + s_{ik} + \pi_j + \tau_{d[i,j]} + \varepsilon_{ijk} \quad (1)$$

Here, μ is a general mean, s_{ik} is the effect of subject k in sequence i , $i = 1, 2, \dots, g$, $k = 1, 2, \dots, n_i$, π_j is the effect of period j , $j = 1, 2, \dots, p$, $\tau_{d[i,j]}$ is the direct effect of the treatment administered in period j to subjects (either patients or healthy volunteers) in group i , and ε_{ijk} is a stochastic disturbance term.

A number of points may be noted about this model.

- The ε_{ijk} terms are often assumed independent. For designs with three or more periods, however, it may be appropriate to allow for autocorrelation within patients over time.
- The model is overparameterized, but it is identifiable contrasts, in particular those of the treatment parameters, which are of interest.
- The treatment parameter is indexed by a functional subscript $d[i,j]$, which identifies it by position (sequence and period). This is because, as discussed above, crossover designs are a form of fractional design: There are t treatments, N patients, and p periods but only $N \times p$ observations. To complete the specification, the function $d[i,j]$ must be separately defined, say by a table that indicates which treatment is given to which sequence group in a given period.
- There is no term for carryover in the model. Jones and Kenward^[6] propose adding a term $\lambda_{d[i,j-1]}$. This form of carryover has been referred to as simple carryover^[1] and is appropriate if carryover lasts only for one period and depends on engendering treatment only (is *not* modified by the perturbed treatment).
- The term s_k can be treated as fixed or random depending on approach. This may or may not make a difference to the resulting inference regarding treatment contrasts: Whether it does so depends on whether interblock information is present and this in turn depends on the balance of the design, whether autocorrelation is allowed or not and whether a carryover term is fitted.^[7]
- Whether or not the *patient* effect is treated as fixed or random, the model does not allow for a true random effect of *treatment*: the possibility that the effect of treatment can vary from patient to patient. The fixed effect approach is extremely common but it can be of interest on occasion to use a random effects approach, in particular in designs where the number of periods exceed the number of treatments.

A popular approach to analyzing crossover trials within the pharmaceutical industry is to apply ordinary least squares using `proc glm`[®] of SAS[®] and treating the patient effect as fixed. Alternatively, the patient effects are sometimes allowed to be random, and this may be conveniently modeled using `proc mixed`[®] of SAS[®]. Sometimes, where this is done, a factor for the sequence itself is introduced to

force the treatment estimate to be a “within-patient” estimate. If this is done, however, between-patient information cannot be recovered.

This issue can be understood simply by considering an AB/BA crossover in which some patients have dropped out at random after the first period. If a fixed effect is included for patients, only patients who have completed both periods will contribute information. However, direct comparison of patients who have received A only with those who have received B only can be made if only the patient effects are allowed to be random (as they must be in any parallel group trial). This will generally contribute a very small amount of information but can in principle be combined with that from patients who have completed both periods using an appropriate approach to analysis as provided, say, by `proc mixed`[®] of SAS[®].

This is a simple example where so-called interblock information is available to be recovered. There are more complex cases. Usually, if carryover is introduced into the model, it means that interblock information can in principle be recovered. An exception is given by models in which simple carryover only is allowed for and the design chosen is such that simple carryover is orthogonal to the treatment effect. For example, such a design is the four-period, two-treatment design using the sequences AABB, BBAA, ABBA, and BAAA. For incomplete block designs, such as illustrated by example 3 above, interblock information is available to be recovered whether or not carryover is fitted.

A general feature of conventional approaches to analyzing crossover trials is that the residual degrees of freedom for error can exceed the number of patients.^[8] Consider, for example, the degrees of freedom for the analysis of variance for a complete blocks design in N patients, p periods, and p treatments. (This sort of design is very common. Examples 1 and 2 above are cases in point with $N = 14$ and $p = 2$ and $N = 72$ and $p = 3$, respectively.) The degrees of freedom for the analysis of variance may be partitioned as follows:

Source	Degrees of freedom		
	In general	Example 1	Example 2
Patients	$N - 1$	13	71
Periods	$p - 1$	1	2
Treatments	$p - 1$	1	2
Error	$Np - N - 2p + 2$	12	140
Total	$Np - 1$	27	215

Now, in the first example, the degrees of freedom for error are 12 and thus inferior to the number of patients. In the second, however, there are nearly twice as many degrees of freedom for error as patients and this signals that strong assumptions are involved.^[8] An alternative approach to using ordinary least squares under such cases can be to reduce the data for a given patient to a contrast of interest and then analyze these contrasts. A similar problem arises with any crossover trial with more than

two periods and where the same treatment, as may be the case in so-called, “*n* of 1 studies,” is repeatedly given to the same patient, this summary measures approach may be particularly valuable.^[1,8] Alternatively a true random effect (multilevel) model can be applied.

MODELING CARRYOVER

There is an enormous literature on adjusting the analysis of crossover trials to allow for the effect of carryover and a corresponding interest in appropriate efficient designs. Most authors have enthusiastically (and usually uncritically) adopted the simple carryover model^[6,9–11] whereby carryover depends only on the engendering treatment and last for one period only. Of course, for the AB/BA design, there are only two periods and the treatment that follows is completely determined by the treatment that precedes. Hence, the simple carryover model is the only one that needs to be considered. Approaches to dealing with carryover in the case of the AB/BA design will be considered below in due course, but in any case, those interested in designing supposedly more efficient crossover trials have usually considered more complex designs. For these more complex designs, simple carryover may not be realistic.

Consider, for example, the design in two periods in which patients are randomized in equal numbers to four sequences AB, BA, AA, and BB.^[12] We can summarize the responses using eight cell means defined by the product of the four sequences and two periods. If we fit a fixed effect for each patient any estimate of the treatment effect (A–B) can be expressed as a linear combination of the four contrasts produced by taking the period 2 cell mean from a given sequence from the corresponding period 1 value. If carryover is ignored altogether, the relevant weights for these four contrasts are 1/2, –1/2, 0, and 0. The patient effects are eliminated by virtue of having used within-cell differences, the period effects are eliminated because the second weight is the negative of the first and it can also be seen by inspection that the treatment difference is appropriately recovered. Let us call this contrast, C_1 .

In the above scheme, the two sequences AA and BB contribute nothing to the estimate of the treatment effect and would appear to be a complete waste of time and resources. If, however, carryover were present and that from A into B were not the same as from B into A, the treatment estimate so formed would have a bias, $\hat{\alpha}$. If it could be assumed that the carryover from A into A were the same as from B into B, this bias could be estimated using the weights 0, 0, 1/2, –1/2 on the four cell mean differences. Let us call this contrast C_2 . A little reflection shows that this second scheme of weights only estimates a carryover effect: patient, period, and treatment effects are eliminated from it. It thus follows that the difference between the first linear combination and the second, $C_1 - C_2$, provides an unbiased estimate in the presence of “simple” carryover.

This does not mean that such a design is useful. On the contrary it is *not* generally useful. The variance of the estimated treatment effect is 4 times what it would be if all patients had been allocated to the first two sequences only. This is a very high price to pay for unbiasedness and modern approaches to data analysis recognize the importance of variance bias trade-offs.^[13] There is, however, a more important criticism, namely, that if carryover occurred, it is extremely unlikely that the carryover from A into A would be the same as from A into B. For example, A might be an active treatment with a response either at steady state (in a multiple trial) or near the top of a dose-response curve. On the other hand B might be a placebo. The carryover from A into B would thus be more important than from A into A.^[1,14–16] There are, in fact, occasions where correcting for simple carryover can increase the bias of the resulting treatment estimate.^[1,16]

When applying the simple carryover model one can distinguish two rather different cases. The first occurs where the design is such that adjusting for simple carryover has no adverse effect on the variance. This is, for example, the case in the four-period design in two treatments using the four sequences AABB, BBAA, ABBA, and BAAB. Note that in this design A follows A twice and B follows A twice and now consider the 16 cell means for this design defined by the cross-classification of sequence and period. A natural and fully efficient estimate of the treatment effect A–B is obtained by multiplying each cell mean corresponding to an A by 1/8, each cell mean corresponding to B by –1/8, and forming the weighted sum. But if simple carryover occurs two of the cell means under A are affected by carryover from a preceding A and so are two of the cell means by B. The weights associated with these cell means add to zero and thus simple carryover is eliminated automatically.

Under such circumstances, fitting simple carryover in the model only reduces the error degrees of freedom and because these will generally be many, there is little reason not to do so. The danger here is rather in assuming that *because* simple carryover has been fitted that all forms of carryover have been eliminated.

The second case is where the design is not fully efficient in the presence of simple carryover. Here, fitting carryover will increase the variance of the treatment estimate. In some cases, it may even increase the bias. It is extremely doubtful whether the simple carryover model is of any value in such cases. A useful review of approaches to modeling carryover in multiperiod designs is given by Matthews.^[17]

An interesting alternative philosophy for adjusting for carryover involves using pharmacokinetic-pharmacodynamic modeling. This is to regard the carryover effect as being a phenomenon of the same sort as the direct effects of treatment and to use a single pharmacokinetic model for both, then linking this to drug response via a suitable dose response models such as, for example, the eMax model.^[18,19]

TESTING FOR CARRYOVER

Until fairly recently an alternative to adjusting for carryover was popular with applied statisticians. This was to perform a preliminary test of (simple) carryover, use an adjusted estimate (or test) of the treatment effect if this preliminary test was significant and an unadjusted test if (as would more usually be the case) this was not. This was a particularly popular approach to analyzing the AB/BA design and will now be described in that connection.^[20,21]

In the presence of carryover, the only unbiased estimate possible from the AB/BA design is that based on first-period data only. Clearly, if the second-period data are discarded, the remaining data have the structure of a parallel group trial and can be analyzed as such. Note that as discussed above, the implicit assumption is that the patient effect is random. An estimate produced under such circumstances will be referred to in the discussion that follows as PAR.^[22]

In the absence of carryover, an unbiased estimate of the treatment effect is provided by weighting the two cell means from the AB sequence with weights $1/2$ and $-1/2$ and the two cell means from the BA sequence with weights $-1/2$ and $1/2$ and then summing. In the discussion that follows, this particular contrast will be referred to as CROS. In the presence of carryover, however, the bias in CROS is $-\lambda/2$, where λ is the difference between the carryover from A into B and from B into A.

An estimate of the *semi* carryover effect, $\lambda/2$, is given by using weights $1/2$ for both cell means in the first sequence and $-1/2$ for both cell means in the second sequence. In other words, it corresponds to the difference between the mean response over both periods in the AB sequence and the corresponding mean response in the BA sequence. Like PAR, this estimate, which will be referred to as CARRY below, is a between-patient estimate, and so to base analyses upon it, a random patient effect must be assumed. It is unbiased for carryover since each sequence mean reflects both treatments and both periods so that the difference between means can only reflect either differences between patients, which are assumed random, or the order in which treatments were administered.

The general situation is given in Table 1. Note that these three estimates satisfy the relationship $PAR = CROS + CARRY$.^[22]

Table 1 Weights for Estimating Effects for an AB/BA Crossover

Sequence	AB		BA	
Treatment	A	B	B	A
PAR	1	0	-1	0
CROS	1/2	-1/2	-1/2	1/2
CARRY	1/2	1/2	-1/2	-1/2
PAR - (CROS + CARRY)	0	0	0	0

In 1965, in an influential paper, Grizzle^[20] proposed a scheme whereby a preliminary test for CARRY was performed at the 10% level. (This higher than usual nominal level was suggested in view of the low power of this test.) If the result was not significant CROS would be used as the basis for tests of the treatment effect at the 5% level. If it was significant PAR would be used, also at the 5% level. This proposal was also clearly described in a further influential paper by Hills and Armitage.^[21] This scheme was very popular for many years, and some pharmaceutical companies had even written SAS macros to perform this two-stage testing procedure automatically. However, in an extremely important paper published in 1989, Freeman^[23] showed that the procedure as a whole does not have the correct implicit nominal size of 5% but, in the case where there is no carryover, has a Type I error rate that lies between 7% and 9.5%.

The reason is the extremely high correlation between PAR and CARRY. In fact, if anything, Freeman's paper understates the problem with the two-stage approach because the pretest is either irrelevant or the conditional Type I error rate of PAR lies between 25% and 50%.^[1,22] In fact, although general medical statistics textbooks continue to recommend this procedure, none of three monographs devoted to the crossover does so^[1,6,9] and its use in drug development and regulation appears to be being abandoned.

It is possible to adjust the two-stage procedure in a number of ways, for example by carrying out the test using PAR at a lower nominal level: Performing this test at the 0.5% rather than the 5% level deals with the problem, for example.^[24,25] However, under such circumstances any power advantages in the face of carryover disappear when compared to the simpler strategy of always using CROS.

It seems plausible that the problems with the two-stage procedure in the case of the AB/BA designs are likely to be present with strategies involving pretesting for more complex designs. Either the carryover effect will be orthogonal to the treatment effect in which case the only loss involved in adjusting for carryover would be residual degrees of freedom, or the effects are not orthogonal in which case similar problems to that with the AB/BA design may occur. In an investigation of the pretesting strategy, Abeysekera and Curnow^[26] came to the conclusion that always adjusting was the best strategy. They implicitly assumed, however, that the simple carryover model would be correct. In a more general investigation allowing for the possibility of an alternative, steady-state model, whereby carryover from a treatment into itself is zero^[14,15] and also allowing for any arbitrary mixture of steady-state and simple carryover model, Senn and Lambrou^[27] came to the opposite conclusion: that never adjusting was the best policy. The field remains controversial and the best advice to the trialist seems to be not to rely on statistical modeling to eliminate carryover.

BAYESIAN APPROACHES

One interpretation of the difficulties that the above approaches to carryover have encountered is that they are too extreme. For example, in the case of the AB/BA design the choice is between an unbiased inefficient estimator PAR or an efficient but potentially biased estimator CROS. The former estimator would correspond roughly to a Bayesian analysis in which uninformative priors were used for both treatment and carryover effects. The latter would apply in a Bayesian analysis in which a completely informative prior was used for carryover, assigning it the value 0 with probability.^[1] (The two-stage procedure is, of course, completely incoherent in a Bayesian sense in that a choice is made between these two extremes on the basis of an amount of information that is quite inadequate to the task in hand.^[28]) A general advantage of Bayesian approaches, however, is that compromise positions are possible or, to reinterpret in a frequentist framework, that bias-variance trade-offs can be achieved naturally.^[13]

A series of papers by Grieve starting 1985 has developed a Bayesian approach to analyzing crossover trials.^[28–32] (An earlier paper by Selwyn et al. considered Bayesian approaches to bioequivalence.^[33]) The general difficulty is that of handling the prior for carryover appropriately. Grieve's approach establishes the appropriate posterior distribution under the assumption that carryover is zero and also making no such assumption. As discussed above, the former corresponds roughly to the CROS analysis and the latter to the PAR analysis, but for the fact that some variance information is recovered from the second period.^[34] However, prior odds for these cases are elicited and these can be updated to produce posterior odds via a Bayes factor. These can be used to mix over the two models and hence produce an integrated posterior distribution for the treatment effect.^[28]

OTHER OUTCOMES

The discussion above has been in terms of the general linear model. This has relatively more importance for the crossover trial than for parallel group trial as the former is restricted in use to chronic diseases for which continuous outcome measurements are common. It may be useful, however, to supplement such analyses with nonparametric techniques. A simple approach for the AB/BA design uses the Wilcoxon-Mann-Whitney test.^[35] A good review of approaches in more complex cases is given by Tudor and Koch.^[36]

Binary outcomes present particular problems in crossover trials because of the difficulty in handling dependence of observations on the same subject. A useful review of various approaches is given by Kenward and Jones^[37] who themselves have developed an approach based on log linear models. The matter is also treated extensively in their

book.^[6] An alternative approach, particularly useful in the more general case where ordered categorical variables are involved, is that of Ezzet and Whitehead.^[38] They generalize the proportional odds model to the crossover context by allowing the true log-odds to have a normal distribution over all patients. It is relatively simple to implement the binary version of this^[39] using *proc nlmixed*[®] of version 8 of SAS[®].

Although survival in the classic sense is not relevant for crossover trials, certain outcome measures may be appropriately analyzed using survival approaches. One example is that of exercise tolerance tests in angina. France et al.^[40] show how such data may be analyzed by establishing patient "preferences:" if a patient "survived" longer under A than B then A is said to be "preferred" for that patient. A tie occurs where both measurements are censored. An alternative approach is given by Feingold and Gillespie.^[41]

BASELINES

Baseline measurements in crossover trials can be of various sorts. There can be baseline measurements taken before the trial begins, before each period of treatment, or even at the end of the trial when it is assumed that all treatment effects have worn off. Various different recommendations have been made for using such measurements to improve inferences. Some authors have suggested using these as a way of adjusting for carryover^[6,9] but this depends on the rather unrealistic assumption that the carryover at the end of a period of treatment will be the same as it was at the start.^[22]

If, however, active washout periods have been used and it can be assumed that they are successful, then baselines may be useful to adjust for random differences between outcome measurements. An important article by Kenward and Roger describes how this may be done in view of the fact that there may be both within and between subject correlations that need to be taken into account.^[42]

HYBRID DESIGNS

Consider clinical trials for infertility in which two treatments are being compared. If a previously infertile couple conceive having been given one treatment, they are hardly likely to seek a second alternative treatment on another occasion. However, if they have failed to conceive in a first period of treatment, they may well be interested in receiving the alternative. It is thus possible to construct clinical trials in which some couples, namely those that fail to conceive in the first period, are crossed over to the alternative therapy. This is therefore an example in which, although it is not possible to cross over all patients, it is possible

to cross over some. Such designs can thus be regarded as hybrids between parallel groups and crossover trials. No doubt there are many other clinical situations that could yield similar data.

Many statisticians will be hesitant about recommending such trials. However, if they are regarded as parallel group trials with some extra data, rather than as crossover trials with missing data, they can be seen in a more positive light. It is crucially important to use a method of analysis that is appropriate for both crossover and parallel group trials. It is thus inappropriate, for example, to treat the patient effect as fixed.

Cohlen et al.^[43] describe an approach to analysis of such trials using time dependent covariates. Makubate, in his doctoral dissertation,^[44] adapted the approach of Ezzet and Whitehead to binary data. Various approaches are discussed by Nason and Follmann.^[45]

FURTHER READING

The books by Jones and Kenward,^[6] Ratkowsky et al.,^[9] and Senn^[1] all give very different perspectives on the crossover trial: The last of these deals most closely with the concerns of the biopharmaceutical statistician. The paper by Hills and Armitage^[19] is an excellent introduction to the AB/BA design although, for reasons explained above, its advice as regards carryover is not sound. The encyclopedia articles by Kenward and Jones^[46] and Senn^[47] may also be useful, as may be a web-based tutorial^[48] and a review of papers that have appeared in *Statistics in Medicine*.^[19] A special issue of *Statistical Methods in Medical Research* was devoted to the crossover trial and has articles on the AB/BA design,^[16] multiperiod designs,^[17] binary data,^[35] nonparametric,^[34] and Bayesian^[30] approaches.

CONCLUSION

Crossover trials are not suitable for all indications and even in indications in which they can sometimes safely be employed, will not be suitable for investigating all treatments. Their use is best restricted to early drug development or for answering specific scientific questions. They are almost never suitable for phase III therapeutic studies. Nevertheless, it would be a grave mistake to conclude, therefore, that they are not useful. Their extreme efficiency makes them very attractive for early phase drug development including pharmacokinetics, bioequivalence, dose-finding, single-dose pharmacodynamic studies and proof of concept. They are also particularly suited for investigating treatment by subject interaction and as such may have an important role to play in the developing field of pharmacogenomics.^[49,50]

Crossover Design: Rank-Based Robust Analysis

M. Mushfiqur Rashid

U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Abstract

This entry develops two rank-based methods for AB/BA crossover designs with baseline values as covariates under the assumption of within-subject exchangeable errors.

Keywords: Covariance; Crossover design; Rank-based method; Rank estimate.

INTRODUCTION

In the simple two-period, two-treatment (A and B) crossover design, subjects are randomly allocated to one of the two treatment sequences AB or BA. Between the treatment periods, there is typically a washout period that is long enough to reduce the potential for carryover of treatment effects from the first period to the second period. It is sometimes possible to make baseline measurements in AB/BA crossover trials. Such baseline measurements are usually made with the object of giving general or background information rather than direct information on treatment effect. If the subjects are subject to individual trend over time and the washout period is long enough compared to the treatment period, the baseline measurements taken at the beginning of each treatment may contain useful information and may be used easily as covariates. Their use may, however, increase directly the precision of measurements made directly on the treatment. Note that baseline measurements are the only covariates that may be used in the analysis of covariance in crossover trials because they are the only covariates that change during the trial and may not therefore be identical for each treatment. In order to use the baseline measurements as the covariates, we need to assume that there are no interactions between the treatments and the periods (see, for example, Refs. [1,2] for discussions). It is worth mentioning that in repeated-measures crossover trials, the observations within each subject are dependent. In the absence of the covariates in the model, besides normal theory inference, there are several nonparametric approaches available in the literature. One can conduct the Mann-Whitney-Wilcoxon test,^[3] the Brown-Mood median test, and the sign test (adjusted) for testing the equality of treatment effects using period differences (see Refs. [1,4,5] for further discussions).

However, there do not appear to be any rank-based tests for the equality of treatment effects (or period effects) in repeated-measures AB/BA crossover trials in the presence of covariates in the model. One may be tempted to use the procedures of Jaeckel^[6] (fixed-effects model approach, based on the joint rankings of all the residuals), which are analogous to the ordinary least squares (OLS) approach for the mixed-effects model in normal theory inference. However, Jaeckel's procedures suffer from loss in efficiency (see "Comparisons of $\hat{\alpha}$ and $\hat{\alpha}^{(P)}$ with $\hat{\alpha}^{(P)}$ When the Baseline Values Are Absent") when the observations within a subject are correlated. This is because the fixed-effects model cannot take into account the dependence of the data within a subject. It is worth mentioning that the analysis of unbalanced mixed models by the OLS approach is not appropriate. For the dependent data, the generalized least squares (GLS) approach gives more efficient inferences than those of the OLS approach.

OVERVIEW

In this entry, we develop two rank-based methods for AB/BA crossover designs with baseline values as covariates under the assumption of within-subject exchangeable errors. In the first method, we will define an objective function for each subject based on the intra-subject ranks of the residuals. Then we will define an overall objective function by taking the sum of all the objective functions. We will obtain R estimates by minimizing this overall objective function. We will then make inferences for the treatment effects and the slope using this overall objective function and the R estimates. In the second method, we will define a single objective function based on period differences for all the subjects for the purpose of making inferences about treatment effects and the slope parameter.

The rest of the entry is organized as follows. In "Model and Assumptions," we discuss the model and its assumptions. "Advantages and Uses of AB/BA Crossover Designs"

Notes: The views expressed in this article are those of the author and not those of the U.S. Food and Drug Administration.

discusses the advantages and uses of crossover designs; “Reasons for Analysis of Covariance in AB/BA Crossover Designs in Clinical Research” discusses reasons for the use of analysis of covariance in AB/BA crossover designs in clinical research. In “Intra-subject Rank-Based Method,” rank-based procedures based on intra-subject ranks of the residuals are developed. In “Rank-Based Methods Using Period Differences,” rank-based methods based on the period differences are developed. “Asymptotic Comparisons” compares the performances of the two rank-based methods presented in this entry—Jaeckel’s method^[4] and normal theory methods. In “An Illustration,” we give an example. The summary is presented in the “Conclusion.”

Model and Assumptions

Suppose, in a two-period, two-treatment crossover study design, that there are n subjects. These n subjects are divided at random into two groups. In the first group, there are n_1 subjects; in the second group, there are n_2 subjects. Let Y_{ijk} and x_{ijk} be the response (outcome) and the baseline value, respectively, corresponding to the i th ($i = 1, 2$) treatment applied on the k th ($k = 1, 2, \dots, n$) subject in the j th ($j = 1, 2$) period. A model for the two-period, two-treatment crossover design in clinical research is described (assuming no treatment by period interaction) as follows:

$$Y_{ijk} = \alpha_i + \pi_j + \beta x_{ijk} + \varepsilon_{ijk} \quad (1)$$

where α_i ($\alpha_1 + \alpha_2 = 0$) is the effect of the i th treatment, π_j ($\pi_1 + \pi_2 = 0$) is the effect of the j th period, β is the slope parameter, and ε_{ijk} is the random error term. It is usually assumed that ε_{ijk} in Eq. 1 is the sum of δ_k ($k = 1, 2, \dots, n_1 + n_2$) and ε_{ijk}^* , where δ_k is the independent normal random variable with a mean of zero and a variance σ_b^2 ($0 < \sigma_b^2 < \infty$) and ε_{ijk}^* is the independent normal random variable with a mean of zero and a variance σ_e^2 . Note that δ_k and ε_{ijk}^* are independent. In this case, Eq. 1 can be termed as an unbalanced mixed model. One may use the SAS procedure PROC MIXED (GLS approach) to make inferences for treatment effects, period effects, and the slope. Note that if we assume that the δ_k is a fixed effect, then we need to use the OLS technique. Note that in the absence of baseline values in Eq. 1, both the OLS and the GLS techniques give identical estimates. In the presence of baseline values in Eq. 1, the GLS inferences differ from the OLS inferences because the OLS approach does not take into account the equicorrelation structure of the within-subject errors.

In the following, we reparameterize Eq. 1 to reflect the dependency of the data within each subject. Let $\theta_{ij} = \alpha_i + \pi_j$. For the k th subject in the sequence AB, Eq. 1 can be written as:

$$\begin{pmatrix} Y_{11k} \\ Y_{22k} \end{pmatrix} = \begin{pmatrix} 1 & 0 & x_{11k} \\ 0 & 1 & x_{22k} \end{pmatrix} \begin{pmatrix} \theta_{11} \\ \theta_{22} \\ \beta \end{pmatrix} + \begin{pmatrix} \varepsilon_{11k} \\ \varepsilon_{22k} \end{pmatrix}$$

For the k th subject in the sequence BA, Eq. 1 can be written as:

$$\begin{pmatrix} Y_{21k} \\ Y_{12k} \end{pmatrix} = \begin{pmatrix} 1 & 0 & x_{21k} \\ 0 & 1 & x_{12k} \end{pmatrix} \begin{pmatrix} \theta_{21} \\ \theta_{12} \\ \beta \end{pmatrix} + \begin{pmatrix} \varepsilon_{21k} \\ \varepsilon_{12k} \end{pmatrix}$$

Let $\varepsilon_k^{(1)} \begin{pmatrix} \varepsilon_{11k} \\ \varepsilon_{22k} \end{pmatrix}$ ($k = 1, 2, \dots, n_1$) and $\varepsilon_k^{(11)} \begin{pmatrix} \varepsilon_{21k} \\ \varepsilon_{12k} \end{pmatrix}$ ($k = n_1 + 1, n_1 + 2, \dots, n_1 + n_2$) be the error vectors for the k th subject in sequences AB and BA, respectively. Without a loss of generality, we suppress the superscripts on the error vectors. In parametric inference, it is assumed that the error vectors $\varepsilon_1, \varepsilon_2, \dots, \varepsilon_{n_1}, \varepsilon_{n_1+1}, \varepsilon_{n_1+2}, \dots, \varepsilon_{n_1+n_2}$ are i.i.d. bivariate normal. If the error vectors are not bivariate normal, alternative techniques such as nonparametric procedures are required. The normal theory F -test for a fixed-effects model is robust against a moderate departure from normality if the design is balanced. However, the problem of robustness in the mixed models is more serious than in the fixed-effects model because there are more assumptions to be met (e.g., normality of the δ_k) in the mixed-effects models (see Ref. [7] for discussions). We assume that the elements of ε_k are exchangeable random variables, that the ε_k values are i.i.d. continuous random vectors with the joint c.d.f. $F(u_1, u_2)$, and that the bivariate density $f(u_1, u_2)$, corresponding to $F(u_1, u_2)$, is continuous in R^2 .

Here, we find R estimates of the model parameters and test the following hypotheses:

1. $H_0^1: \frac{\theta_{11} + \theta_{12}}{2} = \frac{\theta_{21} + \theta_{22}}{2}$ vs. $H_a^1: \frac{\theta_{11} + \theta_{12}}{2} \neq \frac{\theta_{21} + \theta_{22}}{2}$
2. $H_0^2: \frac{\theta_{11} + \theta_{21}}{2} = \frac{\theta_{12} + \theta_{22}}{2}$ vs. $H_a^2: \frac{\theta_{11} + \theta_{21}}{2} \neq \frac{\theta_{12} + \theta_{22}}{2}$
3. $H_0^3: \beta = 0$ vs. $H_a^3: \beta \neq 0$

Note that H_0^1 implies that there are no treatment effects ($\alpha_1 = \alpha_2$), H_0^2 implies that there are no period effects ($\pi_1 = \pi_2$), and H_0^3 implies zero slope.

Advantages and Uses of AB/BA Crossover Designs

Advantages of AB/BA Crossover Designs

In many situations, there are constraints arising from the need to obtain efficacy and safety information in a limited time frame and with limited availability of subjects. When

the variability among subjects is much greater than the variability within subjects, the use of crossover design is appropriate, given that the clinical condition for treatment has a recurrent nature that is essentially equivalent across periods (e.g., discomfort from symptoms from chronic health order, breathing problems in asthma episodes, and problems with hypertension). Note that in these diseases, each patient can be given both treatments in turn, as is the case in the study of certain long-term chronic diseases when the treatments to be evaluated are palliatives designed to lessen pain or to bring comfort or a relief for a particular season rather than to effect a complete cure. One can often argue that carryover effects, if they exist, will be small relative to the treatment effects when there is a suitably long washout period between the treatment periods and when the observations are made at the end of the treatment periods. Note that we will not be able to test for carryover effects under Eq. 1 because we are using baseline values as covariates. Even in the absence of baseline values, it is hard to establish a powerful test for carryover effects. In choosing a crossover design, one needs to consider which assumptions are realistic regarding the nature of the treatment effects. Senn^[1] mentions that no help concerning carryover is to be expected from the data. The solution to this problem lies in designing experiments. The scientist must only use crossover trials in appropriate indications, and must allow for adequate washout.

Note that an important advantage of crossover designs is the requirement of a smaller number of subjects than a design with separate groups of patients for each treatment. One reason for this is that each subject provides information for two treatment periods. Another reason is that the crossover design enables an assessment of treatment comparisons with respect to the usually more sensitive framework of within-subject variability as opposed to that of between-subject variability. By using the crossover design, we reduce or eliminate from treatment contrasts one of the largest uncontrollable sources of variation in a clinical trial, the between-subject variability, and hence we obtain a better interpretation of information obtained from each individual.

Uses of Crossover Designs

The conclusion of the Biometric and Epidemiology Methodology Advisory Committee (BEMAC) of the Food and Drug Administration with respect to the two-period crossover design is that it “is not the design of choice for clinical trials, where unequivocal evidence of treatment effect is required.” Rather, the committee recommended that “in most cases, the completely randomized (or randomized block) design with baseline measurements will be the design of choice because it furnishes unbiased estimates of treatment effects without appeal to modeling assumptions save those associated with the randomization procedure itself.”^[8,9] The BEMAC report encourages the

use of baseline information in the analysis, and recommends the use of change from baseline scores, percentage change from baseline scores, and analysis of covariance. The report states, “If the baseline values vary between sequences or between periods (or both), it is essential that they be included in any analyses” (see Smith^[10] for a further discussion about current regulatory experience concerning crossover trials).

Over half of the 80 crossover trials published in the *British Medical Journal* between January 1980 and April 1988 concerned hypertension, diabetes, angina, and asthma. The design used in most of these trials was the standard AB/BA design (see Jones and Kenward^[4] for further discussion). A survey of 12 large pharmaceutical companies in the United States^[11] revealed a not-too-dissimilar view. Out of 72 crossover trials conducted by these companies over a 5-year period, over half of the trials used the AB/BA design.

A 12-year-old view from the FDA^[12] suggests that the two-period crossover design has not always been viewed negatively. Indeed, of the 22 clinical trials reviewed by Dubey,^[12] crossover designs are recommended in five, permitted in three, permitted but discouraged in eight, and not recommended in six. The U.S. Food and Drug Administration^[13] recommends the use of AB/BA crossover designs for bioequivalence studies. Senn^[1] reports that crossover trials are also popular in single-dose pharmacokinetic and pharmacodynamic studies in healthy volunteers as well as in Phase I tolerability studies and trials for bioequivalence.

Smith^[10] reports that crossover trials play a smaller role as Phase III “pivotal” efficacy trials for most medical indications. However, crossover trials play a major role in the clinical development of a new drug. Phase I and Phase II studies often follow crossover designs.

Grieve^[14] noted, “The saga of the crossover designs for clinical trials is not yet over, and it is healthy that the debate over the applicability of these designs continues, and will continue in the future.”

Reasons for Analysis of Covariance in AB/BA Crossover Designs in Clinical Research

Jones and Wang^[15] point out that if the washout period is such that the investigator may confidently expect that the effect of the previous treatment has been eliminated by the beginning of the following treatment period, and if it is considered that patients may be subjected to individual and specific trends over time (independent of the treatments to which they are allocated), then there may be some value in fitting baseline values in an analysis of covariance.

It is worth mentioning that the analysis of covariance technique is an efficient procedure for addressing two issues in clinical trials. The first is the reduction of variability in treatment effect and thereby the production of narrower confidence intervals and more powerful tests. The second

is the clarification of the extent of treatment effects in the presence of any baseline imbalance between the treatment groups. If it is suspected that there are treatment-by-period interactions, the researcher could use the procedures of Koch,^[3] which are based on gain score (response minus baseline). However, the gain score method can sometimes give different results than those of an analysis of covariance (see Grieve^[14] for parametric analysis using the gain score method and for a related discussion).

INTRA-SUBJECT RANK-BASED METHOD

In this section, we consider R estimation and rank tests based on intra-subject ranks of the residuals.

R Estimation

In this subsection, we develop R estimators and their asymptotic distributions. We will use a sum of Jaeckel-type dispersion functions^[6] to develop the rank-based inference. The role of this dispersion function is similar to the sum of squared errors (SSE) in the least squares theory. We will use the R estimators to carry out tests and confidence intervals.

Let $\theta = (\theta_{11}, \theta_{22}, \theta_{21}, \theta_{12})'$. A measure of dispersion for the k th subject, following the idea of Jaeckel,^[6] is:

$$D_k(\underline{\Delta}) = \sqrt{12} \sum_{j=1}^2 \sum_{i=1}^2 n_{ij}^{(k)} \left[\frac{R_{ijk}}{3} - \frac{1}{2} \right] W_{ijk} \quad (2)$$

where $n_{ij}^{(k)} = 1$ if the i th treatment is applied at the j th period on the k th subject and $n_{ij}^{(k)} = 0$ otherwise, $W_{ijk} = Y_{ijk} - \theta_{ij} - \beta x_{ijk}$, and R_{ijk} is the intra-subject rank of W_{ijk} .

It can be shown that $D_k(\underline{\Delta})$ is non-negative, continuous, location-free, and convex in $\underline{\Delta}$. It is worth mentioning that the coefficient of the residuals W_{ijk} lies in the interval $(-1/2, 1/2)$, and this coefficient (of W_{ijk}) assigns a weight proportional to the difference between its rank (between two elements) and the average rank. Because $D_k(\underline{\Delta})$ is a piecewise linear function of the residuals, the outliers enter into the dispersion function in a linear fashion.

In practice, individual subjects are different (not similar). Therefore the subjects may differ in their responses to a drug. By using the intra-subject ranks of the residuals, we are removing the subject effect. As mentioned earlier, in crossover designs, it is usually assumed that the variation among subjects is much greater than the variation within subjects, and so the estimation of model parameters on using intra-subject ranks is appropriate. We will show that inferences based on intra-subject rank-based methods are more efficient than those based on normal theory methods (for heavy-tailed and heavier-tailed distributions) and rank-based methods (for heavier-tailed distributions) using period differences.

Using Eq. 2, we can construct a combined dispersion function for Eq. 1 as follows:

$$D(\underline{\Delta}) = \sum_{k=1}^n D_k(\underline{\Delta}) \quad (3)$$

$D(\underline{\Delta})$ in Eq. 3 is non-negative, continuous, location-free, and convex in $\underline{\Delta}$. Although the ranking of the residuals is done within each subject separately, there is a “borrowing of strength” from across the subjects because the R estimates are obtained by minimizing the combined dispersion function. Under the assumption that the subjects are similar, a model that pulls the estimates together is used. Note that the sum of Jaeckel-type dispersion function^[6] (based on within rankings) has been used to incorporate concomitant variables in one-way repeated-measures designs (see Ref. [16]), a nested error regression model (see Ref. [17]), and incomplete block clinical trials (see Ref. [18]).

We obtain an R estimator of $\underline{\theta}$ by minimizing $D(\underline{\Delta})$. Let $\hat{\underline{\Delta}} \in \Gamma$, where $\Gamma = [\underline{\Delta}: D(\underline{\Delta}) = \text{a minimum}]$. One can use the Nelder-Mead algorithm^[19] to minimize $D(\underline{\Delta})$ (see the NLPNMS procedure of PROC IML of SAS for a detailed discussion of the Nelder-Mead algorithm).

Recently, Kloke et al.^[20] have developed rank-based estimation and associated inferences for linear models with cluster correlated errors. Their method is based on the joint (single) ranking (JR) of residuals of all the subjects. In a future work, the JR method will be applied to 2×2 and higher order crossover designs.

Kloke et al.^[20] has also obtained the asymptotic relative efficiency (ARE) results (for balanced designs) for several common error distributions comparing the JR estimator with the intra-subject rank-based estimator, which is based on a Friedman-type of ranking within blocks (many rankings: MR) and was proposed by Rashid.^[21] Except in extreme cases the JR estimator does quite well. For example, the JR estimator is more efficient than the MR estimator at the normal distribution except when the block size is large or when the correlation is high. They confirmed these ARE results by a Monte Carlo simulation study. This simulation study also confirms that for heavier tailed distributions (contaminated normals) the JR estimator is more efficient than least-square (LS). It will be of interest to see how the two methods (JR and MR) perform in the context of cross-over designs.

In order to obtain the asymptotic distribution of the R estimators, we need the asymptotic distribution of the gradient of the dispersion function. In the following, we develop the asymptotic distribution of the gradient of the dispersion function.

Let

$$\underline{S}(\underline{\theta}, \underline{\beta}) = [s_{11}(\underline{\theta}, \underline{\beta}), s_{22}(\underline{\theta}, \underline{\beta}), s_{21}(\underline{\theta}, \underline{\beta}), s_{12}(\underline{\theta}, \underline{\beta}), s_5(\underline{\theta}, \underline{\beta})]' \quad (4)$$

be the negative of the gradient of $D(\underline{\theta}, \underline{\beta})$. The domain of $D(\underline{\theta}, \underline{\beta})$ consists of polygonal subsets, in each of which

$D(\underline{\theta}, \beta)$ is linear in $\underline{\theta}$ and β . Therefore the partial derivatives exist almost everywhere and are given by the coefficients of the parameters in the dispersion function.

The elements of the negative of the gradient $\underline{S}(\underline{\Delta})$ of $D(\underline{\Delta})$ are given by:

$$\begin{aligned} s_{11}(\underline{\theta}, \beta) &= \sqrt{12} \sum_{k=1}^{n_1} \left[\frac{R_{11k}}{3} - \frac{1}{2} \right] \\ s_{22}(\underline{\theta}, \beta) &= \sqrt{12} \sum_{k=1}^{n_2} \left[\frac{R_{22k}}{3} - \frac{1}{2} \right] \\ s_{12}(\underline{\theta}, \beta) &= \sqrt{12} \sum_{k=1}^{n_2} \left[\frac{R_{12k}}{3} - \frac{1}{2} \right] \\ s_{21}(\underline{\theta}, \beta) &= \sqrt{12} \sum_{k=1}^{n_2} \left[\frac{R_{12k}}{3} - \frac{1}{2} \right] \\ s_5(\underline{\theta}, \beta) &= \sqrt{12} \sum_{k=1}^n \sum_{i=1}^2 \sum_{j=1}^2 n_{ij}^{(k)} \left[\frac{R_{ijk}}{3} - \frac{1}{2} \right] x_{ijk} \end{aligned}$$

Under the true value $\underline{\Delta} = \underline{0}$ and exchangeability of errors, the ranks R_{ijk} within each subject are uniformly distributed over the permutations of the integers 1 and 2. Therefore under exchangeability of the errors:

$$E_0[R_{ijk}] = \begin{cases} \frac{3}{2} & \text{if } n_{ij}^{(k)} = 1 \\ 0 & \text{otherwise} \end{cases}$$

Also

$$\text{var}_0[R_{ijk}] = \begin{cases} \frac{1}{4} & \text{if } n_{ij}^{(k)} = 1 \\ 0 & \text{otherwise} \end{cases}$$

Further

$$\text{COV}_0[R_{ijk}, R_{i'j'k'}] = \begin{cases} -1/4 & \text{if } (i, j) = (1, 1) \text{ and } (i', j') = (2, 2) \\ -1/4 & \text{if } (i, j) = (2, 1) \text{ and } (i', j') = (1, 2) \\ 0 & \text{otherwise} \end{cases}$$

Thus $E_0[S(\underline{0})] = 0$

Let $\underline{\Sigma} = \text{cov}_0[(1/\sqrt{n})\underline{S}(\underline{0})]$.

Then

$$\underline{\Sigma} = (\sigma_{ii'}) = \begin{pmatrix} \frac{1}{3} \\ \frac{1}{3} \end{pmatrix} \begin{bmatrix} \frac{n_1}{n} & \frac{-n_1}{n} & 0 & 0 & \frac{\mu_1}{n} \\ \frac{-n_1}{n} & \frac{n_1}{n} & 0 & 0 & \frac{-\mu_1}{n} \\ 0 & 0 & \frac{n_2}{n} & \frac{-n_2}{n} & \frac{\mu_2}{n} \\ 0 & 0 & \frac{-n_2}{n} & \frac{n_2}{n} & \frac{-\mu_2}{n} \\ \frac{\mu_1}{n} & \frac{-\mu_1}{n} & \frac{\mu_2}{n} & \frac{-\mu_2}{n} & \frac{\eta}{n} \end{bmatrix} \quad (5)$$

where $\mu_1 = x_{11} - x_{22}$, $\mu_2 = x_{21} - x_{12}$.

$$\eta = 2 \sum_{j=1}^2 \sum_{i=1}^2 \sum_{k=1}^n n_{ij}^{(k)} (x_{ijk} - \bar{B}_{.k})^2 (> 0) \text{ and } \bar{B}_{.k} = (1/2) \sum_{i=1}^2 \Sigma_i = \frac{1}{2} \sum_{j=1}^2 n_{ij}^{(k)} x_{ijk}.$$

We assume

$$\lim_{n \rightarrow \infty} \text{cov}_0[n^{-1/2} \underline{S}(\underline{0})] = \lim_{n \rightarrow \infty} \left(\frac{1}{n} \right) \underline{\Sigma} = A = (a_{ii'}) \quad (6)$$

Let $x_{ijk}^4 < L (< \infty)$. Note that $\underline{S}(\underline{0})$ can be written as a sum of n bounded and independent random vectors. By a multivariate central limit theorem, it can be shown that under the true value $\underline{\Delta}^0 = \underline{0}$:

$$n^{-1/2} \underline{S}(\underline{0}) \xrightarrow{D} \text{MVN}(0, A) \quad (7)$$

as $n \rightarrow \infty$, where MVN stands for multivariate normal.

Note that the sum of the first three rows of A is zero. Therefore the matrix A is singular. Further, the diagonal elements are positive because they are variances of the components of $\underline{S}(\underline{\theta}, \beta)$ and we assume that $a_{ii} = \lim_{n \rightarrow \infty} (\sigma_{ii}/n) > 0$. Note that the rank of $\underline{\Sigma}$ is 3. The role of $\underline{S}(\underline{\Delta})$ in this entry is similar to the scores in maximum likelihood techniques.

Next, we derive the asymptotic distribution of $\hat{\underline{\Delta}}$. Using arguments similar to those given in Rashid and Nandram,^[16] it can be shown that:

$$\sqrt{n}(\hat{\underline{\Delta}}) \text{ and } \sqrt{n}\{(\tau/n)A^{-1}\underline{S}(\underline{0})\} \text{ are asymptotically equivalent} \quad (8)$$

where

$$\tau = \left[\frac{1}{\{\sqrt{12} \int_{-\infty}^{\infty} f(\varepsilon, \varepsilon) d\varepsilon\}} \right] < \infty \quad (9)$$

and $f(\cdot, \cdot)$ is the bivariate density of the two components of the error vector.

It follows from Eqs. 7 and 8, under the true value $\underline{\Delta}^0$, that:

$$\sqrt{n}[\hat{\underline{\Delta}} - \underline{\Delta}^0] \xrightarrow{D} \text{MVN}(\underline{0}, \tau^2 A^{-1}) \text{ as } n \rightarrow \infty \quad (10)$$

Note that there are model-checking procedures available for the nonparametric nested error regression model.^[17] Similar procedures can be applied to Eq. 1.

Rank Tests

In this section, we develop the drop-in-dispersion test based on the R estimators. We need an R estimator $\hat{\underline{\Delta}}_H$ of $\underline{\Delta}$ under the hypothesis $a'\underline{\Delta} = 0$. We also need the asymptotic distribution of the R estimator of $\hat{\underline{\Delta}}_H$. Let $\hat{\underline{\Delta}}_H$ minimize $D(\underline{\Delta})$ under $a'\underline{\Delta} = 0$. Using arguments similar to those given in Rashid,^[20] we have:

$$\sqrt{n} \hat{\underline{\Delta}}_H = \sqrt{n}[\hat{\underline{\Delta}} - A^{-1}a(a'A^{-1}a)^{-1}a'\hat{\underline{\Delta}}] + o_p(1) \quad (11)$$

Note that the reduced model R estimator $\hat{\Delta}_H$ has a representation (asymptotically) similar to reduced model estimators in the least squares analysis. For testing $\underline{a}'\underline{\Delta} = 0$, we compare $D(\hat{\Delta})$ with $D(\hat{\Delta}_H)$. It can be shown that under $\underline{a}'\underline{\Delta} = 0$:

$$D^* = \frac{2[D(\hat{\Delta}_H) - D(\hat{\Delta})]}{\hat{\tau}} \quad (12)$$

follows approximately a chi-square distribution with 1 *df* for large n . For $H_0^1: (\theta_{11} + \theta_{12})/2 = (\theta_{21} + \theta_{22})/2$, we take $\underline{a}' = (1/2, -1/2, -1/2, 1/2, 0)$.

The D^* test is analogous to $-2 \log \Lambda$ in maximum likelihood techniques. It is also analogous to F -tests in the normal theory inference (see Rashid and Nandram^[16] for the drop-in-dispersion test in one-way repeated-measures designs with a changing covariate). The proof of Eq. 12 goes along the same lines given in Rashid and Nandram^[16] (see also Rashid^[20]).

For testing a general linear hypothesis based on scores $\underline{S}(\underline{\Delta})$ evaluated at the reduced model estimate $\hat{\Delta}_H$, the reader is referred to Rashid.^[18] The scores test is analogous to Rao's scores test in the maximum likelihood technique.

Note that the results of this entry are derived under the assumption that the number of subjects is large. Rashid^[22] conducted a small-scale simulation study for the drop-in-dispersion test for multigroup repeated-measures designs (without covariates) with exchangeable errors within each subject. Based on this simulation study, it is recommended that the chi-square percentile be used for the D^* tests when $10 \leq n_1 \leq 15$ and $10 \leq n_2 \leq 15$.

One can construct a $100(1 - \gamma)\%$ confidence interval for any estimable function of $\underline{\Delta}$ using Eq. 9. Let $\underline{a}'\underline{\Delta}$ be a contrast in $\underline{\Delta}$. An approximate $100(1 - \gamma)\%$ confidence interval for $\underline{a}'\underline{\Delta}$ is:

$$\underline{a}'\hat{\Delta} \pm \left(z \frac{\gamma}{2} \right) \hat{\tau} \sqrt{\left(\underline{a}' \sum - \underline{a} \right) / n} \quad (13)$$

Estimation of τ

As mentioned earlier, the parameter $\tau = 1/[\sqrt{12} \{ \int_{-\infty}^{\infty} f(\varepsilon, \varepsilon) d\varepsilon \}]$ plays a role similar to $\sigma^2(1 - \rho)$ in parametric repeated-measures analysis. It can be shown that the parameter $1/[\sqrt{12\tau}]$ is the density of $d_k = [\varepsilon_{11k} - \varepsilon_{22k}]$ (or $d_k = [\varepsilon_{21k} - \varepsilon_{12k}]$) at zero for $k = 1, 2, \dots, n_1$ (or for $k = 1, 2, \dots, n_2$). Thus d_k ($k = 1, 2, \dots, n_1, n_1 + 1, \dots, n_1 + n_2$) are n i.i.d. random variables having continuous and symmetric distributions, each with the median at zero. Hence estimating τ involves estimating the inverse of the density function at zero. Following Bloch and Gastwirth,^[23] we can obtain a consistent estimator of the inverse of the density function at zero as:

$$g = \left\{ \frac{n}{(2m)} \right\} [d_{(n, [n/2]+m)} - d_{(n, [n/2]-m+1)}] \quad (14)$$

where $m = pn^{4/5}$ as $n \rightarrow \infty$. Thus a consistent estimator of τ is $\hat{\tau} = g / \sqrt{12}$. It is recommended that p be taken to be 0.5. In practice, we will replace ε_{ijk} s by the residuals.

RANK-BASED METHODS USING PERIOD DIFFERENCES

In this section, we develop the inferences for treatment effect based on the period differences. We will also discuss the estimation of a scale parameter. In normal theory inference, treatment effect is estimated using the period differences from each subject. The unbiasedness of this resulting estimate rests on the validity of the assumption that there is no treatment-by-period interaction. Our method in this section will also be based on the period differences. We also assume that there is no treatment-by-period interaction. First, we define an objective function for estimating the treatment effect and the slope. Then we develop the asymptotic distribution of these estimates under the full model and the reduced model (under the hypothesis). Then we develop rank tests.

Let $U_k^{(I)} = Y_{22k} - Y_{11k}$ and $U_k^{(II)} = Y_{12k} - Y_{21k}$ be the period differences of the responses for sequences I and II, respectively. Similarly, let $V_k^{(I)} = x_{22k} - x_{11k}$ and $V_k^{(II)} = x_{12k} - x_{21k}$ be the period differences of the baseline values for sequences I and II, respectively. Then Eq. 1 can be written separately for each sequence as:

$$\begin{aligned} U_k^{(I)} &= \alpha + \pi + \beta V_k^{(I)} + e_k^{(I)}, \quad k = 1, \dots, n_1 \\ U_k^{(II)} &= -\alpha + \pi + \beta V_k^{(II)} + e_k^{(II)}, \quad k = 1, \dots, n_2 \end{aligned}$$

where $\alpha = \alpha_2 - \alpha_1$ (treatment effect), $\pi = \pi_2 - \pi_1$ (period effect), $e_k^{(I)} = \varepsilon_{22k} - \varepsilon_{11k}$, and $e_k^{(II)} = \varepsilon_{12k} - \varepsilon_{21k}$. Note that, by using the period differences, we remove the subject effects. Without a loss of generality, we suppress the superscripts in $e_k^{(I)}, e_k^{(II)}, U_k^{(I)}, U_k^{(II)}, V_k^{(I)},$ and $V_k^{(II)}$. Note that e_k s are i.i.d. continuous random variables with a median of zero and a variance $2\sigma^2(1 - \rho)$. Using Wilcoxon scores, we define the Jaeckel dispersion function^[6] based on the joint ranks of the residuals $u_k - \psi_k \alpha - \pi - \beta v_k$ as follows:

$$D^{(P)}(\alpha, \beta) = \sqrt{12} \sum_{k=1}^n \left[\frac{R_k^{(P)}}{n+1} - \frac{1}{2} \right] W_k^{(P)} \quad (15)$$

where $W_k^{(P)} = u_k - \psi_k \alpha - \pi - \beta v_k$, $R_k^{(P)}$ is the rank of the k th residual $W_k^{(P)}$ among n residuals, and:

$$\psi_k = \begin{cases} 1 & \text{if } k = 1, 2, \dots, n_1 \\ -1 & \text{if } k = n_1 + 1, \dots, n_1 + n_2 \end{cases}$$

The term π (the period effect) has dropped out of the dispersion function because ranks of the residuals do not change by inclusion or exclusion of π . Thus by ranking

the residuals (over all the subjects) based on the period differences, we remove the period effect.

One may define two dispersion functions separately for Eq. 1 by using ranks (intraperson) of the n residuals corresponding to two periods, and then by adding the two dispersion functions to obtain a combined dispersion function. By doing this, we will be able to remove the period effects, but we will not be able to remove the subject effects from the estimates of the slope and treatment effects. The n subjects in Eq. 1 represent an effort to reduce experimental errors and prevent misleading comparisons of “apples and oranges.” In such a comparison, a difference in treatment effects would be confounded with basic characteristics (e.g., smoking, age) of the subjects, the latter being of little or no interest in a particular experiment. It would be foolish to compare the response of treatment 1 at period 1 of one subject with the response of treatment 2 at period 1 of another subject when the two subjects differ in a particular characteristic (see, for example, Hollander and Wolfe^[24] for a detailed discussion). Thus the use of intracomponent (e.g., intraperson) rankings for inferences for the repeated-measures designs might not be feasible.

Note that $D^{(p)}(\alpha, \beta)$ is non-negative, continuous, location-free, and convex in $(\alpha, \beta)'$. We can thus obtain an R estimator of $(\alpha, \beta)'$ by minimizing $D^{(p)}(\alpha, \beta)$. Let $(\alpha, \beta) \in \Gamma^{(p)}$, where $\Gamma^{(p)} = [(\alpha, \beta) : D^{(p)}(\alpha, \beta) = \text{a minimum}]$.

In order to obtain the asymptotic distribution of the R estimators, we need the asymptotic distribution of the gradient of the dispersion function. In the following, we develop the asymptotic distribution of the gradient of the dispersion function.

Let $\underline{S}^{(p)}(\alpha, \beta) = [s_1^{(p)}(\alpha, \beta), s_2^{(p)}(\alpha, \beta)]'$ be the negative of the gradient of $D^{(p)}(\alpha, \beta)$. Then:

$$\underline{S}^{(p)}(\alpha, \beta) = \left(\sqrt{12} \sum_{k=1}^n \psi_k \left[\frac{R_k^{(p)}}{n+1} - \frac{1}{2} \right], \sqrt{12} \sum_{k=1}^n v_k \left[\frac{R_k^{(p)}}{n+1} - \frac{1}{2} \right] \right)'$$

Under $(\alpha^0, \beta^0)' = \underline{0}$, $R_k^{(p)}$ s are uniformly distributed over the integer 1 through n . Therefore:

$$E_0[R_k^{(p)}] = 0, \quad \text{var}[R_k^{(p)}] = \frac{n^2 - 1}{12}, \text{ and} \\ \text{cov}[R_k^{(p)}, R_{k'}^{(p)}] = \frac{-(n+1)}{12} \quad (k \neq k')$$

It can be shown that under $(\alpha^0, \beta^0)' = \underline{0}$:

$$n^{-1/2} \underline{S}^{(p)}(0, 0) \xrightarrow{D} \text{BVN}(0, A^{(p)}) \quad (16)$$

as $n \rightarrow \infty$, where BVN stands for bivariate normal and:

$$A^{(p)} = (a_{ii}^{(p)}), \quad a_{11}^{(p)} = \lim_{n \rightarrow \infty} 4n_1 n_2 / \{n(n+1)\} \\ a_{12}^{(p)} = a_{21}^{(p)} = \lim_{n \rightarrow \infty} \frac{1}{n+1} \left(\sum_{k=1}^n \psi_k v_k - \frac{1}{n} \sum_{k=1}^n v_k \sum_{k=1}^n \psi_k \right)$$

$$a_{22}^{(p)} = \lim_{n \rightarrow \infty} \frac{1}{n+1} \sum_{k=1}^n (v_k - \bar{v})^2$$

We assume that the matrix $A^{(p)}$ is positive definite. Note that Eq. 16 can be proven using arguments similar to those given in Hettmansperger,^[25] and Hettmansperger and McKean.^[26]

Using arguments similar to those given in Jaeckel,^[6] it can be shown that:

$$\sqrt{n}(\hat{\alpha}^{(p)}, \hat{\beta}^{(p)})' \text{ and } \sqrt{n} \left\{ \left(\frac{\tau_1}{n} \right) (A^{(p)})^{-1} \underline{S}^{(p)}(0, 0) \right\} \text{ are} \\ \text{asymptotically equivalent} \quad (17)$$

where

$$\tau_1 = \frac{1}{\left\{ \sqrt{12} \int_{-\infty}^{\infty} f_1^2(e) de \right\}} \quad (18)$$

and $f_1(\cdot)$ is the density of $e_k = (\varepsilon_{22k} - \varepsilon_{11k})$ (or $\varepsilon_{12k} - \varepsilon_{21k}$) (see also Hettmansperger^[25] and Heiler and Willers^[27] for further details).

It follows from Eqs. 16 and 17 and under the true value $(\alpha^0, \beta^0)'$:

$$\sqrt{n}[(\hat{\alpha}^{(p)}, \hat{\beta}^{(p)})' - (\alpha^0, \beta^0)'] \xrightarrow{D} N[\underline{0}, \tau_1^2 (A^{(p)})^{-1}] \\ \text{as } n \rightarrow \infty \quad (19)$$

Now consider the estimation of α when $\beta = 0$. In this case, the dispersion function Eq. 15 will reduce to:

$$D^{(p)}(\alpha, 0) = \sqrt{12} \sum_{k=1}^n \left[\frac{R_k^{(p)}}{n+1} - \frac{1}{2} \right] W_k^{(p)}$$

where $W_k^{(p)} = u_k - \psi_k \alpha$ and $R_k^{(p)}$ is the rank of the k th residual $W_k^{(p)}$ among n residuals. Let $\hat{\alpha}_H$ minimize $D^{(p)}(\alpha)$. It follows from Eq. 19 that under the true value α^0 :

$$\sqrt{n}(\hat{\alpha}_H^{(p)} - \alpha^0) \xrightarrow{D} N \left[0, \frac{\tau_1^2}{a_{11}^{(p)}} \right] \text{ as } n \rightarrow \infty \quad (20)$$

Next, consider the estimation of β when $\alpha = 0$. In this case, the dispersion function Eq. 15 will reduce to:

$$D^{(p)}(0, \beta) = \sqrt{12} \sum_{k=1}^n \left[\frac{R_k^{(p)}}{n+1} - \frac{1}{2} \right] W_k^{(p)}$$

where $W_k^{(p)} = u_k - \beta$ and $R_k^{(p)}$ is the rank of the k th residual $W_k^{(p)}$ among n residuals. Let $\hat{\beta}_H^{(p)}$ minimize $D^{(p)}(\beta)$. It follows from Eq. 19 that under the true value β^0 :

$$\sqrt{n}(\hat{\beta}_H^{(p)} - \beta^0) \xrightarrow{D} N \left[0, \frac{\tau_1^2}{a_{22}^{(p)}} \right] \text{ as } n \rightarrow \infty \quad (21)$$

In the following, we develop rank tests for no treatment effects and zero slope. It can be shown that under $H_0^1: \alpha = 0$:

$$D_1^* = \frac{2[D^{(P)}(0, \hat{\beta}_H^{(P)}) - D(\hat{\alpha}^{(P)}, \hat{\beta}^{(P)})]}{\hat{\tau}_1} \quad (22)$$

follows approximately a chi-square distribution with 1 df. It can further be shown that under $H_0^3: \beta = 0$:

$$D_3^* = \frac{2[D^{(P)}(\hat{\alpha}_H^{(P)}, 0) - D^{(P)}(\hat{\alpha}^{(P)}, \hat{\beta}^{(P)})]}{\hat{\tau}_1} \quad (23)$$

follows approximately a chi-square distribution with 1 df.

The proofs of drop-in-dispersion tests D_1^* and D_3^* go along the lines of McKean and Hettmansperger^[28] (see also Hettmansperger^[25]).

Like the Wilcoxon-Mann-Whitney test, it is recommended that the chi-square percentile be used for the drop-in-dispersion test when both $n_1 \geq 10$ and $n_2 \geq 10$. In fact, the drop-in-dispersion test (D_1^*) is asymptotically equivalent to the test (the aligned rank test) based on the scores $s_1^{(P)}(0, \hat{\beta}^{(P)})$. The aligned rank test for testing $H_0^1: \alpha = 0$ is based on the reduced model residuals $W_k^{(P)} = u_k - \Psi - \hat{\beta}_H^{(P)} v_k$ (see Hettmansperger^[25] for aligned rank tests for the linear model with i.i.d. errors). In the absence of β in Eq. 1, the test ($H_0^1: \alpha = 0$), based on the scores $s_1^{(P)}(0, 0)$, reduces to the Wilcoxon-Mann-Whitney test proposed by Koch.^[3]

Because the distribution of e_k is symmetric about zero, π can be estimated by the median of the Walsh averages $(W_k^{(P)} + W_{k'}^{(P)})/2$, $k < k' = 1, 2, \dots, n$ (see Randles and Wolfe^[29]) where $W_k^{(P)} = u_k - \Psi - \hat{\beta}^{(P)} v_k$. Thus a nonparametric estimate of π is:

$$\hat{\pi} = \text{median}_{k < k'} \left\{ \frac{W_k^{(P)} + W_{k'}^{(P)}}{2} \right\}$$

Also we will be able to test $H_0^2: \pi = 0$ by the Wilcoxon signed rank test using the residuals $W_k^{(P)} = u_k - \Psi - \hat{\beta}^{(P)} v_k$. Because in crossover designs we are interested mainly in the treatment effect, we will not pursue the inferences concerning period effect.

Note that there are model-checking procedures available for the nonparametric linear model with i.i.d. errors. For example, see Refs. [30,31] for detailed procedures.

Estimation of τ_1

Note that $e_1, e_2, \dots, e_n$ are i.i.d. random variables. Let the density of e_k be $f_1(e)$. Then $\tau_1 = 1/(\sqrt{12}\gamma_1)$, where $\gamma_1 = \int_{-\infty}^{\infty} f_1^2(e) de$. The random variable e_k follows a continuous and symmetric distribution with median at zero. Hence estimating τ_1 involves estimating the inverse of the density function at zero. Following Bloch and Gastwirth,^[23] we can obtain a consistent estimator of the inverse of the density function at zero as:

$$\frac{1}{\hat{\gamma}_1} = \left\{ \frac{n}{(2m)} \right\} [e_{(n, [n/2]+m)} - e_{(n, [n/2]-m+1)}] \quad (24)$$

where $e_{(k)}$'s are the ordered e_k 's and $m = pn^{4/5}$ as $n \rightarrow \infty$. Thus a consistent estimator of τ_1 is $\hat{\tau}_1 = 1/[\sqrt{12}\hat{\gamma}_1]$. It is recommended that ρ be taken to be 0.5. In practice, we will replace the $e_{(k)}$'s by the residuals $\hat{e}_k^{(P)} = \hat{W}_k^{(P)} = u_k - \Psi_k \hat{\alpha}^{(P)} - \hat{\beta}^{(P)} v_k$. Thus the parameter τ_1 can be estimated by $\hat{\tau}_1 = 1/[\sqrt{12}\hat{\gamma}_1]$.

ASYMPTOTIC COMPARISONS

In this section, we compare the performances of R , $R^{(P)}$, and GLS methods in terms of asymptotic variances when the baseline values are absent. We also discuss the performances of R , $R^{(P)}$, and GLS methods on empirical grounds when the baseline values are present. We further compare both $\hat{\alpha}$ and $\hat{\alpha}^{(P)}$ with $\hat{\alpha}^{(J)}$, where $\hat{\alpha}^{(J)}$ is the R estimate of α using Jaeckel procedures,^[6] assuming that ε_{ijk} in Eq. 1 is the sum of δ_k (the fixed subject effect) and ε_{ijk}^* (the random error term with $\text{var}(y_{ijk}) = \text{var}(\varepsilon_{ijk}^*) \sigma^2$ when the baseline values are absent).

Comparisons of $\hat{\alpha}$, $\hat{\alpha}^{(P)}$, and $\hat{\alpha}_{\text{GLS}}$ Without the Baseline Values

In this section, we consider the asymptotic relative efficiencies of the three estimators $\hat{\alpha}$ (based on the within rankings), $\hat{\alpha}^{(P)}$ (based on the period differences), and $\hat{\alpha}_{\text{GLS}}$ in the absence of baseline covariate in Eq. 1.

It is interesting to note that it is the asymptotic distribution of the test under a sequence of alternatives that determines the asymptotic distribution of the estimator. In most cases, the empirical power is consistent with the results predicted by the asymptotic relative efficiency (Pitman efficiency).

Without a loss of generality, we assume that there is no covariate in Eq. 1. The asymptotic variances are as follows:

$$\begin{aligned} \text{var}(\sqrt{n}\hat{\alpha}) &= \frac{3n^2\tau^2}{4n_1n_2} \\ \text{var}(\sqrt{n}\hat{\alpha}^{(P)}) &= \frac{n(n+1)\tau_1^2}{4n_1n_2} \\ \text{var}(\sqrt{n}\hat{\alpha}_{\text{GLS}}) &= \frac{2n^2\sigma^2(1-\rho)}{4n_1n_2} \end{aligned}$$

Bivariate Normal Distribution

For the bivariate normal distribution with correlation coefficient ρ and variance σ^2 , we have:

$$\tau^2 = \frac{\pi\sigma^2(1-\rho)}{3} \quad \text{and} \quad \tau_1^2 = \frac{2\pi\sigma^2(1-\rho)}{3}$$

Therefore

$$\begin{aligned}\lim_{n \rightarrow \infty} \left\{ \frac{\text{var}(\sqrt{n}\hat{\alpha}^{(P)})}{\text{var}(\sqrt{n}\hat{\alpha})} \right\} &= 0.666 \\ \lim_{n \rightarrow \infty} \left\{ \frac{\text{var}(\sqrt{n}\hat{\alpha}_{\text{GLS}})}{\text{var}(\sqrt{n}\hat{\alpha})} \right\} &= 0.636 \\ \lim_{n \rightarrow \infty} \left\{ \frac{\text{var}(\sqrt{n}\hat{\alpha}_{\text{GLS}})}{\text{var}(\sqrt{n}\hat{\alpha}^{(P)})} \right\} &= 0.955\end{aligned}$$

We see that the F -test and $\hat{\alpha}_{\text{GLS}}$ are examples of procedures that have high power and efficiency for the normal model.

It should be pointed out that normal theory-based procedures are highly unstable. Only one observation is enough to alter the conclusions reached by an F -test. The $\hat{\alpha}$ and the corresponding drop-in-dispersion test are quite stable (see “An Illustration” for an example).

Bivariate t Distribution

The variance of t random variable with scale parameter σ and degrees of freedom η_1 is $\eta_1 \sigma^2 / (\eta_1 - 2)$. For the bivariate t -distribution with correlation coefficient ρ , scale parameter σ , and degrees of freedom η_1 , we get:

$$\begin{aligned}\tau^2 &= \left[\sqrt{\eta_1} \Gamma\left(\frac{\eta_1}{2}\right) / \Gamma\left(\frac{\eta_1 + 1}{2}\right) \right]^2 \frac{\pi \sigma^2 (1 - \rho)}{6} \\ \text{and } \tau_1^2 &= \left[\sqrt{\eta_1} \Gamma\left(\frac{\eta_1}{2}\right) / \Gamma\left(\frac{\eta_1 + 1}{2}\right) \right]^2 2\pi \sigma^2 \frac{(1 - \rho)}{6}\end{aligned}$$

Therefore

$$\begin{aligned}\lim_{n \rightarrow \infty} \left\{ \frac{\text{var}(\sqrt{n}\hat{\alpha}^{(P)})}{\text{var}(\sqrt{n}\hat{\alpha})} \right\} &= 0.666 \text{ for } \eta = 3, 4, 5, 8; \text{ and} \\ \lim_{n \rightarrow \infty} \left\{ \frac{\text{var}(\sqrt{n}\hat{\alpha}_{\text{GLS}})}{\text{var}(\sqrt{n}\hat{\alpha})} \right\} &= 1.62, 1.12, 0.96, 0.8 \\ \lim_{n \rightarrow \infty} \left\{ \frac{\text{var}(\sqrt{n}\hat{\alpha}_{\text{GLS}})}{\text{var}(\sqrt{n}\hat{\alpha}^{(P)})} \right\} &= 2.55, 1.77, 1.52, 1.26 \text{ for } \eta = 3, 4, 5, 8\end{aligned}$$

Thus both $\hat{\alpha}$ and $\hat{\alpha}^{(P)}$ do much better than the GLS estimator $\hat{\alpha}_{\text{GLS}}$ for the heavy-tailed distributions. However, $\hat{\alpha}^{(P)}$ does better than $\hat{\alpha}$ for the heavy-tailed distributions. It is expected that the R estimates obtained by minimizing $D(\Delta)$ and $D^{(P)}(\alpha, \beta)$ will be more robust than normal theory counterparts because the influence of the outliers is linear rather than quadratic.

Bivariate Double Exponential Distribution

Consider a bivariate double exponential distribution with $\sigma^2 = 2$ and $\rho = 0.5$. We can generate bivariate double exponential variables ε_1 and ε_2 with $\sigma^2 = 2$ and $\rho = 0.5$ by defining $\varepsilon_1 = x_1 - x_2$ and $\varepsilon_2 = x_1 - x_3$, where x_1, x_2, x_3 , and

x_4 are i.i.d. exponential random variables with a mean of one. Thus the p.d.f. of $\varepsilon_1 - \varepsilon_2$ is again double exponential. Therefore $\tau = 1/[\sqrt{12}/2]$ and $\tau_1 = 1/[\sqrt{12}/4]$. Thus:

$$\begin{aligned}\lim_{n \rightarrow \infty} \left\{ \frac{\text{var}(\sqrt{n}\hat{\alpha}^{(P)})}{\text{var}(\sqrt{n}\hat{\alpha})} \right\} &= 1.33 \\ \lim_{n \rightarrow \infty} \left\{ \frac{\text{var}(\sqrt{n}\hat{\alpha}_{\text{GLS}})}{\text{var}(\sqrt{n}\hat{\alpha}^{(P)})} \right\} &= 1.5 \\ \lim_{n \rightarrow \infty} \left\{ \frac{\text{var}(\sqrt{n}\hat{\alpha}_{\text{GLS}})}{\text{var}(\sqrt{n}\hat{\alpha})} \right\} &= 2\end{aligned}$$

Thus for the heavier-tailed distributions (e.g., double exponential), we prefer the tests of “Intra-subject Rank-Based Method” rather than those of “Rank-Based Methods Using Period Differences.” This is not surprising because the ranking is done within subjects; thus the ranks (in “Intra-subject Rank-Based Method”) are bounded and thereby again nullify the effects of outliers. We cannot discard the intra-subject rank-based tests because of its poor performance when the data are normally distributed. The intra-subject ranking is an attempt to eliminate a nuisance effect because of the subject’s characteristics. Usually the purpose of clinical trials is not to test for subject effects but to concentrate on testing treatment differences (see, for example, Senn and Auclair^[32] for further discussion).

Empirical Comparisons of $\hat{\alpha}$ and $\hat{\alpha}^{(P)}$ with $\hat{\alpha}_{\text{GLS}}$ in the Presence of Baseline Values

As to be expected, if the normal error structure holds, there are minor differences between the rank-based method and the GLS method. Recall that the GLS estimators are functions of σ_b^2 and σ_e^2 . Thus to obtain the point estimates, estimates of these variance components must be obtained. Thus while the GLS estimates require estimated variance components, they are not required for the rank-based estimates. Therefore the rank-based procedures are expected to show better performance than the GLS counterparts.

We know that the GLS estimators are no longer the best when the estimates of variance components (σ_b^2 and σ_e^2) are substituted in expressions for the estimates of α , π , and β . The R estimates, on the other hand, are not functions of the variance components. So the rank-based methods have the potential to perform better than the GLS methods even when the model based on the normal structure holds; and they (rank-based methods) do even better, especially when this structure does not hold.

Rashid and Nandram^[17] performed a small-scale simulation study for comparing the performances of the GLS procedures and the intracluster R estimator-based procedures for the nested error regression models in the context of small area estimation. They noted that there were gains in precision using the R estimates when normality is tenuous. The simulation study they conducted indicated

that if there were outliers occurring uniformly in either tails of the error distributions, the rank-based (intracluster) method would be superior to the GLS method. Similar results were indicated for skewed error distributions.

We expect that rank-based procedures based on the period differences would perform better than GLS procedures if there were outliers occurring uniformly in either tails of the error distribution. Similar conclusions would hold for skewed error distributions.

Comparisons of $\hat{\alpha}$ and $\hat{\alpha}^{(P)}$ with $\hat{\alpha}^{(J)}$ When the Baseline Values are Absent

First we discuss how to estimate $\hat{\alpha}^{(J)}$ where $\hat{\alpha}^{(J)}$ is the Jaekel's R -estimate of α based on fixed effects model. We assume that ε_{ijk} in Eq. 1 is the sum of δ_k (the fixed subject effect) and ε_{ijk}^* (the random error term) with $\text{var}(y_{ijk}) = \text{var}(\varepsilon_{ijk}^*) = \sigma^2$. Jaekel^[6] proposed an objective function, known as the dispersion function, to compute the R estimates of the fixed-effects model (i.e., the linear models with i.i.d. errors). The dispersion function of Jaekel^[6] is based on the joint ranking of all the residuals. Following Jaekel,^[6] we define a dispersion function for the fixed-effects version of Eq. 1 based on Wilcoxon scores as follows:

$$D(\alpha_1, \alpha_2, \pi_2, \pi_2, \underline{\delta}) = \sqrt{12} \sum_{k=1}^n \sum_{j=1}^2 \sum_{i=1}^2 n_{ijk} \times \left[\frac{R_{ijk}^{(J)}}{n+1} - \frac{1}{2} \right] W_{(ijk)}^{(J)}$$

where $W_{ijk}^{(J)} = y_{ijk} - \alpha_i - \pi_j - \delta_k - \beta x_{ijk}$, $R_{ijk}^{(J)}$ is the rank of the (ijk) th residual $W_{ijk}^{(J)}$ among $2n$ residuals, $\underline{\delta} = (\delta_1, \delta_2, \dots, \delta^n)'$ is a vector of fixed subject effects ($\sum_k \delta_k = 0$), and $n_{ij}^{(k)} = 1$ if the i th treatment is applied at the j th period on the k th subject and zero otherwise. The R estimates and drop-in-dispersion tests can be developed analogously as done in "Rank-Based Methods Using Period Differences."

Let $\alpha = \alpha_2 - \alpha_1$. It can be shown (see Ref. [25]) that when the covariate is absent in the model:

$$\text{var}(\sqrt{n}\hat{\alpha}^{(J)}) = \frac{n(n+1)(\tau_1^*)^2}{4n_1n_2}$$

Where

$$\tau_1^* = \frac{1}{\sqrt{12} \int_{-\infty}^{\infty} f_*^2(\varepsilon) d\varepsilon}$$

and $f_*(\cdot)$ is a probability density function of ε_{ijk}^* .

Comparisons of $\hat{\alpha}$ with $\hat{\alpha}^{(J)}$

It is sufficient to compare $\hat{\alpha}$ with $\hat{\alpha}^{(J)}$ in the absence of the covariate. Thus the ARE of $\hat{\alpha}$ with respect to $\hat{\alpha}^{(J)}$ is given by:

$$\lim_{n \rightarrow \infty} \left\{ \frac{\text{var}(\sqrt{n}\hat{\alpha}^{(J)})}{\text{var}(\sqrt{n}\hat{\alpha})} \right\} = \left(\frac{2}{3} \right) \left\{ \frac{\int_{-\infty}^{\infty} f_*^2(\varepsilon) d\varepsilon}{\int_{-\infty}^{\infty} f(\varepsilon, \varepsilon) d\varepsilon} \right\}^2$$

For the normal and t distributions, the preceding ARE reduces to $2/\{3(1-\rho)\}$. That is, when $\rho \geq 0.35$, the ARE of $\hat{\alpha}$ with respect to $\hat{\alpha}^{(J)}$ for the normal distribution is greater than one. For moderate and high values of ρ ($0.35 \leq \rho < 1$), the methods of "Intra-subject Rank-Based Method" are preferred over the methods of Jaekel.^[6]

For the double exponential distribution with $\rho = 0.5$ and $\sigma^2 = 2$, it can be shown that the ARE of $\hat{\alpha}$ with respect to $\hat{\alpha}^{(J)}$ is 2.67.

Comparisons of $\hat{\alpha}^{(P)}$ with $\hat{\alpha}^{(J)}$

It can be shown that the ARE of $\hat{\alpha}^{(P)}$ with respect to $\hat{\alpha}^{(J)}$ is given by:

$$\lim_{n \rightarrow \infty} \left\{ \frac{\text{var}(\sqrt{n}\hat{\alpha}^{(P)})}{\text{var}(\sqrt{n}\hat{\alpha}^{(J)})} \right\} = \frac{\left\{ \int_{-\infty}^{\infty} f_*^2(\varepsilon) d\varepsilon \right\}^2}{\left\{ \int_{-\infty}^{\infty} f_1(\varepsilon) d\varepsilon \right\}^2}$$

For the normal and t distributions, the preceding ARE reduces to $1/(1-\rho)$. Thus for $\rho > 0$ (which is expected in repeated-measures data), the ARE of $\hat{\alpha}^{(P)}$ with respect to $\hat{\alpha}^{(J)}$ for the normal distribution is greater than one. This result is analogous to the corresponding normal theory result, because in normal theory inference, the parameter $1/(1-\rho)$ also measures the efficiency of a paired design with respect to an unpaired design.

For the double exponential distribution with $\rho = 0.5$ and $\sigma^2 = 2$, it can be shown that the ARE of $\hat{\alpha}^{(P)}$ with respect to $\hat{\alpha}^{(J)}$ is 2.

In clinical crossover trials, the data are repeated measures; therefore the methods of this entry are very applicable. Therefore we will not pursue the method of Jaekel^[6] for repeated-measures data.

AN ILLUSTRATION

The analysis methods will be illustrated using the data set from a 2×2 crossover trial described in Patel.^[33] The trial included 17 subjects with mild to moderate bronchial asthma in which the acute effects of single doses of two active drugs were compared. We will label the treatments A and B. All medications are discontinued 12 hr prior to receiving the trial treatments. The response measurement used to compare the two treatment groups is forced expiratory volume in 1 sec (FEV₁). Subjects were divided at random into two groups, and those in the first group received the treatments in the order AB. It has been recently reported (see protocol 9 of the CIBA-GEIGY Brethine program, Basle, and Ref. [34]) that the baseline value for subject 11 prior to period 1 is 2.05. In fact, this subject did not improve at all after the medication. It has also been reported that the response for subject 8 on period 2 is 2.43 instead of 2.41. The observed responses are given in Tables 1 and 2. Because Patel found that there were no

interactions between the treatments and the periods, we use the baseline values as covariates.

We will consider two cases. In the first case, we use all the data points. In the second case, we delete subject 9, which is considered to be an outlier (mild) by Jones and Kenward^[4] and Kenward and Jones.^[35] In fact, Kenward and Jones^[35] deleted subject 9 from their analyses.

Patel's Data Without the Outlier

We consider two cases. The first case is the analysis in the presence of baseline values. The second case is the analysis without the baseline values.

Inferences in the Presence of Baseline Values

Using the subroutine NLPNMS of PROC IML of SAS, we compute the R estimates of the treatment effects and the slope. We have used PROC MIXED (PROC GLM) of SAS to compute the GLS (OLS) estimates.

First we consider the inferences of β . The estimate of β , its estimated standard error, and the value of the test statistic, along with the p value corresponding to each

Table 3 Patel's Data: Inference for the Slope

Method	β	SE	$F_{\beta = 0/D_{\beta = 0}}^*$	p value
OLS	1.3959	0.2953	22.34	0.0003
OLS _{WTO}	1.1075	0.1786	38.44	0.0001
R	1.1846	0.1304	27.07	< 0.0001
R_{WTO}	1.1833	0.2664	15.67	< 0.0001

R	0.2119	0.0450	19.87	< 0.0001
R_{WTO}	0.2115	0.0665	13.53	0.0002
$R^{(P)}$	0.2337	0.0289	64.64	< 0.0001
$R_{WTO}^{(P)}$	0.2117	0.0310	50.93	< 0.0001

WTO = without outlier; P = period.

method (OLS, GLS, R , and $R^{(P)}$), are given in Table 3. All methods show that there is a significant linear relationship between the response and the baseline values. However, the OLS method gave the highest standard error. The rest of the method gave comparable estimated standard errors. The OLS estimate is also much different from the GLS estimate. However, the GLS estimate and $\hat{\beta}$ are very close.

Second, we consider the inference for the treatment effect. We report the estimate, its estimated standard error, and the test statistic, along with the p value, in Table 4. We see that the OLS and the GLS estimates are very close. The $\hat{\alpha}$ and $\hat{\alpha}^{(P)}$ are very close but differ from both $\hat{\alpha}_{OLS}$ and $\hat{\alpha}_{GLS}$. The OLS estimate has the highest estimated standard error, whereas $\hat{\alpha}^{(P)}$ has the lowest estimated standard error. All the methods show that there is a significant difference between the two treatments.

Inferences Without the Baseline Values

We present the estimates of the treatment effect, its estimated standard errors, and the values of the test statistic, along with the p values for each method (GLS, R , and $R^{(P)}$), in Table 5 (assuming that there is no covariate effect in Eq. 1). The two R estimates are very close. However, $\hat{\alpha}^{(P)}$ has a smaller estimated standard error than $\hat{\alpha}$. The OLS/GLS estimate has the highest estimated standard

Table 5 Patel's Data: Inference for the Treatment Effects Without the Baseline

Method	$\alpha_2 - \alpha_1$	SE	$F_{\alpha_1 = \alpha_2} / D_{\alpha_1 = \alpha_2}^*$	p value
OLS/GLS	0.2552	0.1184	4.64	0.0478
OLS _{WTO} /GLS _{WTO}	0.1750	0.0873	4.01	0.0650
R	0.1521	0.0839	5.26	0.0217
R_{WTO}	0.1521	0.0798	3.68	0.0550
$R^{(P)}$	0.1772	0.0496	9.31	0.0022
$R_{WTO}^{(P)}$	0.1494	0.0542	6.61	0.0100

WTO = without outlier; P = period.

error. All the methods show that there is a significant difference between the two treatments.

Comparing Tables 4 and 5, we see that the inclusion of the baseline values in the model resulted in smaller standard errors (estimated) of the estimates. Thus we obtain more precise estimates of the effect when the baseline values are included in the model as covariates.

Patel's Data Without the Outlier

An investigation of the residuals (for period 1) from the OLS technique has shown that the residuals are not normally distributed. Also, subject 9 seems to be an outlier. We have therefore dropped this subject from the analysis.

Inferences in the Presence of Baseline Values

Using the subroutine NLPNMS of PROC IML of SAS, we compute the R estimates of the treatment effects and the slope. The estimates are presented under the subscript WTO (without outlier). First we consider the inferences of β . The estimate of β , its estimated standard errors, and the value of the test statistic, along with the p value for each method (OLS, GLS, R , and $R^{(P)}$), are given in Table 3. All the methods show that there is a significant linear relationship between the response and the baseline values. However, the intra-subject rank-based method (R) gives the largest standard error. The OLS estimate has the next largest standard error. The GLS estimate has the smallest estimated standard error, although it is very close to that of $\hat{\beta}^{(P)}$. Note that without the outlier, the normal probability plot of the OLS residuals (from the first period) shows that the data are normally distributed. However, all the estimators, except $\hat{\beta}$, are affected by the outlier. The most affected is the OLS estimate. However, the $\hat{\beta}^{(P)}$ is also affected by the outlier, but not as much as the OLS estimate. The GLS and OLS estimates are very close.

Second, we consider the inference for the treatment effect. The estimate of α , its estimated standard errors, and the value of the test statistic, along with the p value for each method (OLS, GLS, R , and $R^{(P)}$), are given in Table 4. Note that $\hat{\alpha}$ and $\hat{\alpha}^{(P)}$ are very close but differ from both the OLS and the GLS estimates. Note also that $\hat{\alpha}$ is not

affected by the outlier at all. The OLS/GLS estimate has the highest estimated standard error, whereas $\hat{\alpha}^{(P)}$ has the lowest estimated standard error.

Inferences Without the Baseline Values

The estimate of α , its estimated standard errors, and the value of the test statistic, along with the p value for each method (GLS, R , and $R^{(P)}$), are given in Table 5. Only the $R^{(P)}$ method shows that there is a significant difference between the two treatments. The intra-subject rank-based method shows borderline significance (p value of 0.055). The OLS/GLS method gives a p value of 0.0650, which shows that there is a numerical trend in favor of treatment 2 over treatment 1.

CONCLUSION

The results of this entry provide a robust alternative to the parametric analysis of repeated-measures AB/BA crossover over designs with baseline values as covariates. The rank-based tests have applications to biopharmaceutical studies, clinical trials, and other scientific experiments. One of the problems commonly encountered in bioavailability studies is that the data set sometimes contains some extremely large and/or small observations known as outliers. These outlying data may have dramatic effects on the bioequivalence test. Results with and without the outlying observations could be totally opposite. It is therefore appropriate to use rank-based methods, which are less affected by outliers.

The maximum likelihood and the GLS approaches are based on the assumption that the data follow a multinormal theory model. Clearly, this is a strong assumption and needs to be investigated for each case. One possibility would be to consider the use of transformations. But the transformation will distort the model and its assumptions. A nonparametric test would be required, for example, if the data could not be transformed to satisfy the usual (e.g., normality) assumptions. It is worth mentioning that both the GLS and the maximum likelihood approaches require the finiteness of the covariance matrix of the error vectors. In the rank-based methods, we do not need the finiteness of the covariance matrix of the error vectors. For this reason, the procedures proposed in this entry will have an attractive appeal to data analysts.

Because the estimates of the variances σ_e^2 and σ_b^2 are required in the GLS approach for the estimation of the fixed-effects part of the mixed model, it is important that they be non-negative. Also, the estimators of σ_e^2 and σ_b^2 will affect the variance of the estimators of the fixed effects. Searle^[36] noted, "These are difficulties of the mixed model: for unbalanced data, estimating fixed effects in the presence of variance components, and estimating variance components themselves" in the context of ANOVA-based estimates.

The default variance component estimation used by PROC MIXED of SAS is the restricted maximum likelihood estimators (REML) algorithm. Also, the computer algorithm BMDP-5V provides REML estimators of the variance components for a mixed model. For balanced experiments, REML estimates are identical to the estimates obtained from expected mean squares, provided all estimates are positive. It is important to obtain non-negative estimates of the variance components because they are used in the analysis of fixed effects. The REML estimation procedure does not, however, include estimating the fixed effects. Nevertheless, having obtained the estimators of the variance components using REML, one would undoubtedly use these to obtain maximum likelihood estimates for the fixed effects after replacing the variance components in the maximum likelihood equations by their estimates (see Searle^[36] for further discussion). On the other hand, the *R* estimates developed in this entry are easy to compute using the PROC IML of SAS. They do not suffer from the problems mentioned by Searle in the context of the GLS technique.

In this entry, we have assumed that there is no treatment-by-period interaction because we have used baseline values as covariates. In a future work, we will consider a rank-based approach to incorporate the baseline as responses in the presence of period-by-treatment interaction in the model (see Refs. [34,35] for normal theory approach). Koch^[37] suggests that the evaluation of treatment-by-interaction still requires attention, regardless of whether such interaction is because of carryover effects or not. It is also mentioned by Jones and Wang^[15] that carryover effects in AB/BA crossover designs should not always be ignored. Until now in the absence of baseline values, both in normal theory and in nonparametric inferences, the tests (the *t*-test and the Wilcoxon-Mann-Whitney test) for no period-by-treatment interaction are based on the subject totals. The tests based on the subject totals are not powerful because these procedures do not eliminate the subject effects from the test statistics.

Abstract

This entry discusses alternative design strategies that are intended to address ethical or practical concerns when it is deemed unethical or infeasible to randomize all subjects to study interventions.

INTRODUCTION

The randomized design is the preferred method for assessing the efficacy of treatments. Randomization of all subjects should be employed whenever possible. Randomization, in principle, serves at least three important purposes: (i) it avoids known and unknown biases on average; (ii) it helps convince others that the trial was conducted properly; and (iii) it is the basis for the statistical theory that underlies hypothesis tests and confidence intervals.^[1]

Randomization of all subjects has been criticized, however, because it may raise ethical concerns or practical limitations in certain situations. Ethical tensions may arise, for example, when strong a priori (though inconclusive) information favors the experimental treatment, when the disease is potentially life-threatening, and when randomization does not explicitly incorporate subjects' baseline clinical need or their willingness to incur risk.^[2,3] Examples that have stirred considerable debate about the ethics of the randomized design include the controversies about the release of drugs for AIDS,^[4] the availability of drugs for cancer treatment,^[5] and the use of extracorporeal membrane oxygenation (ECMO) for neonatal intensive care.^[6,7]

A second potential drawback of the randomized design occurs in instances when randomization is not feasible or practical. Such situations may arise in health services or outcomes research where, for example, a health education program is to be targeted only to people who need it.^[8] An evaluation and comparison between managed care and usual care could be made feasible if high users of health-care utilization receive managed care only and low users of health-care utilization receive usual care only. A study concerned with the effect of a letter as an intervention to control health-care costs could be made practical if the letter is sent only to physicians with high billed charges per subscriber, whereas those with lower billed charges per subscriber don't receive a letter.^[9] In these contexts, economic constraints and logistical barriers may dictate

that an experimental intervention is neither practical nor efficient for those who do not need it or who are not the targeted candidates. Moreover, treatment allocation that reflects actual practice allows for testing the effectiveness of the intervention—its benefit in a real-life setting, as opposed to its benefit in a controlled setting.

This entry discusses alternative design strategies that are intended to address ethical or practical concerns when it is deemed unethical or infeasible to randomize all subjects to study interventions. These design strategies may be called *cutoff* designs because they involve, at least in part, the assignment of subjects to treatments based on a cutoff score on a quantitative baseline variable that measures clinical need, severity of illness, or some other relevant measure. What follows is an overview of cutoff designs.

DESCRIPTION OF THE REGRESSION-DISCONTINUITY (RD) DESIGN

The most basic of cutoff designs is the regression-discontinuity (RD) design^[8,10–13] in which a baseline indicator, for example severity of illness, can be used to assign subjects to an intervention. All subjects below a cutoff point on the baseline indicator receive one treatment, while all subjects above it receive another treatment. The history of the RD design is found in the social sciences, specifically in program evaluation. It has been employed to evaluate the effects of compensatory education, being on the Dean's list, a criminal justice program, a health education program on serum cholesterol, accelerated math training, and the NIH Career Development Award.^[14] In these scenarios randomization of subjects was not a viable alternative. A comprehensive history of the regression-discontinuity design in three academic disciplines—psychology, statistics, economics—has been published.^[15]

The traditional RD design is a single-cutoff quasi-experimental design that involves no random assignment.

The RD design received its name from the “jump,” or discontinuity, at the cutoff in the regression line of baseline and outcome (follow-up) scores that occurs when there is a treatment effect. Figure 1 depicts a RD design with a hypothetical 10-point treatment effect (reduction). All subjects with scores above 20 on the baseline assignment indicator are most in the need of the intervention and hence are automatically assigned to the test (experimental) treatment, whereas those with scores of 20 or less (those less in need) are automatically assigned to control treatment.

As Fig. 1 illustrates, the outcome scores of the test treatment group (those scoring above the cutoff) are lowered by an average of 10 points from where they would be expected in the absence of a treatment effect. The solid lines show the predicted regression lines for a 10-point effect, and the dashed lines show the expected regression lines for patients in a treatment group if they were given the other intervention instead.

The baseline assignment covariate should be measured on at least an ordinal scale; it is more desirable, though, to have a continuous (ratio-level or interval-level) baseline assignment variable. Baseline and outcome may be the same or different, the cutoff can be placed anywhere along the baseline measure (as long as there are sufficient numbers in the control group), the direction of improvement can be positive or negative for either variable, the treatment groups could have more than two levels, and the response variable can be discrete or continuous.

VALIDITY OF THE RD DESIGN

Under the assumption that the outcome-baseline functional form is correctly specified, the RD design results in an unbiased estimate of treatment effect. An unbiased estimate of treatment effect is obtained because the assignment process is known perfectly and controlled for

Fig. 1 Regression-discontinuity design with a 10-point treatment effect

in the analysis.^[10] Formal statistical derivations proving this unbiasedness are found elsewhere.^[14–18] Like the randomized experimental (RE) design, the RD design gives a known probability of assignment to treatments. It is imperative, though, that the cutoff assignment rule be followed strictly. If subjects are misclassified, then the treatment effect is likely to be biased.

It can also be demonstrated that the estimate of treatment effect in the RD design, like the RE design, remains unbiased when random measurement error in the observed, fallibly measured baseline covariate is considered.^[14–18] The reason for this is, once the fallibly measured observed baseline scores are known, treatment assignment is completely determined and hence independent of anything else, including the perfectly measured true baseline scores, in the RD design. Similarly, in the RE design, treatment assignment is completely determined by a randomization scheme and hence independent of anything else.

Regression to the mean, which naturally emanates from random measurement error in the observed baseline covariate, does not therefore affect the estimate of treatment effect in both the RD design and the RE design. Fig. 2 graphically shows the impact of regression to the mean, or, equivalently, random measurement error in the observed covariate, in the case of no treatment effect when the same variable is measured at baseline and follow-up. In the absence of a treatment effect, and with no other effects that may change a subject's score at follow-up, the true regression line should be a 45-degree line beginning at the origin. Regression to the mean causes the fitted regression line to be attenuated by an amount proportional to the reliability coefficient of the baseline covariate; therefore, the sample regression coefficient of the baseline covariate on the outcome measure is biased, but the sample regression coefficient of the treatment effect is not.^[14,16]

The RE design is robust in giving unbiased estimates of treatment effect when the true functional form between the baseline covariate and the outcome measure is not correctly specified. On the other hand, the RD design is not robust here. The most critical step in obtaining an unbiased estimate of effect in the RD design lies in modeling

Fig. 2 Regression to the mean: randomized and regression-discontinuity designs

this true functional form correctly. The true functional form, however, is not known in the RD design because of missing data. As shown in Fig. 1, which assumes a linear functional form, the extrapolated regression line of the control group (dashed line, right) if this group's subjects were given treatment instead is assumed to continue in the same linear way as its fitted line (solid line, left). The extrapolated regression line of the test-treated group (dashed line, left) if this group's subjects were given control treatment is assumed to continue in the same way as its fitted line (solid line, right). There is no way to know prospectively whether the form or the slope of the lines in the region of missing data will be the same as that in the region of observed data.

SPECIFYING THE FUNCTIONAL FORM

One suggestion for helping to arrive at the correct functional form is to use a polynomial backward elimination regression approach.^[19] Another suggestion uses empirical Bayesian methods to overcome situations when the outcome and baseline relationship may not be linear, as when true baseline scores are not normally distributed.^[20,21] A third approach, which can be used with either of the other two approaches, is to fit a regression line over a wider range of the baseline-outcome distribution, resulting in less extrapolation and hence a more valid fit. This last approach can be achieved by combining the RD design with the RE design, resulting in a cutoff design with randomization.

COMBINING RD AND RE DESIGNS

A regression-discontinuity design can be described as a cutoff design without randomization. This design can also be coupled with a randomized design. For instance, patients who score within the middle range of scores on a baseline severity-of-illness indicator (e.g., those moderately ill) are randomized to either one of two treatments, while patients who score below a given cutoff value on this indicator (e.g., those most ill) are automatically assigned to the novel treatment and patients who score above another, higher cutoff value (e.g., those least ill) are assigned to the control treatment. Another type of cutoff design, for instance, would have subjects below the single cutoff point (e.g., the most ill) randomized to either treatment, whereas those above it (e.g., the least ill) are automatically assigned to control treatment. These are only two possible design variations that can combine cutoff assignment and random assignment. Other variations are mentioned elsewhere.^[22,23]

Combining the RE design and the RD design may give advantages over either design alone.^[22–24] Relative to the RE design, this hybrid design may be better suited to address ethical or practical concerns, may result in a larger eligible and diverse sample, and may better address

the effectiveness (as opposed to the efficacy) of interventions in particular circumstances. Compared with the RD design, RD-RE design has enhanced validity and improved statistical power.

ILLUSTRATION: COCAINE PROJECT

To illustrate the combined design, we describe a cocaine project, conducted by Havassy and colleagues at the University of California at San Francisco, that applied the RD-RE design instead of the completely randomized design, which was considered neither ethical nor feasible. The study included about 500 patients with cocaine addiction. The objective of the study was whether inpatient (intensive) rehabilitation showed better improvement, and by how much, over outpatient rehabilitation. The baseline assignment covariate was based on a weighted composite of four scales: (i) employment and legal status, (ii) family relationship and recovery, (iii) alcohol and drug history, and (iv) psychological status. Higher scores indicated more clinical need for the more intensive (inpatient) rehabilitation. The primary outcome variable was the same variable measured at follow-up.

Figure 3 portrays how patients may be allocated into inpatient or outpatient rehabilitation in this setting. All patients who score above 60—those most severely ill or most in need—are automatically assigned to inpatient rehabilitation; all patients who score below 40—those least ill or least in need—are automatically assigned to outpatient rehabilitation; and patients who score in between 40 and 60, inclusive—those moderately ill or in need—are randomized to either inpatient rehabilitation or outpatient rehabilitation. Note that it is this cutoff interval of randomization that distinguishes the RD-RE design from the RD design, which instead has a cutoff point(s) with no randomization.

Like Figs. 1 and 3 has solid lines representing the predicted regression lines and dash lines representing the extrapolated regression lines, showing a constant improvement from inpatient rehabilitation over outpatient rehabilitation. An analysis of covariance model, with the baseline assignment measure and the treatment group variable as predictors, would be a correct model to fit the fitted lines in Figs. 1 and 3. An analysis of variance model, which excludes the baseline assignment variable, should not be fit as it would result in a biased estimate of treatment effect. Although linear relations are highlighted in these two figures, cutoff designs are not restricted to a linear baseline-outcome relationship; higher-order terms (e.g., quadratic or cubic terms), transformations on baseline or outcome variables, and interaction terms may also be fitted.

In a simulation study, several RD-RE design variations, of which the basic design in Fig. 3 is the simplest one, were evaluated and compared among themselves, along with the traditional RD design and the traditional RE design.^[22,23] An unbiased main treatment effect was found for all these designs.

Fig. 3 Illustration of a combined randomized and regression-discontinuity design

Figure 4 shows one of the more advanced RD-RE designs that may be useful for accommodating varying amounts of resources. One cutoff interval has its bounds at 45 and 55; the other cutoff interval has its bounds at 40 and 60. Both intervals are symmetric around 50. Because the two intervals have different widths, they include different numbers of randomized patients, with the wider interval containing more randomized subjects. As subjects accrue into a study, investigators of a clinical site may favor one interval of randomization over the other in order to address the cost implications of having a shortage or surplus of hospital beds for inpatient rehabilitation. Or one interval may be preferred because it is more commensurate with a hospital's level of resources and expertise with respect to a given treatment.

MODELING AND ANALYZING CUTOFF DESIGNS

The RD-RE combination can be modeled and analyzed with the polynomial backward elimination approach mentioned in section “Specifying the Functional Form” for the RD design. Specifically, the initial model equation is

$$y + b_{int} + (b_{trt})^*z + (b_{xcut})^*xcut + (b_{xcut})^*(xcut)^2 + (b_{xcut}3)^*(xcut)^3 + (b_{linint})^*(z^*xcut) + (b_{linquad})^*(z^*xcut^2) + (b_{lincub})^*(z^*xcut^3) + error$$

Fig. 4 Randomized and regression-discontinuity design with two cutoff intervals

where

y = outcome measure

$xcut$ = baseline assignment covariate minus a baseline value at which to measure the treatment effect (e.g., the middle value in a cutoff interval in a RD-RE design or the cutoff value itself in a RD design)

z = binary treatment group variable

$bint$ = intercept estimator

$btrt$ = treatment effect estimator

$bxcut$ = linear slope estimator

$blincut$ = linear interaction estimator

$error$ = sample regression error term.

The other regression coefficients are the coefficients for powers of “ $xcut$ ” higher than 1 and for their corresponding higher-order interactions. The same set of assumptions that apply to linear regression (for continuous responses) and to logistic regression (for discrete responses) also applies here.

The modeling strategy first tests the significance of each regression coefficient separately beginning with the higher-order interaction terms (i.e., the cubic interaction is tested first, followed by the quadratic interaction, and then linear interaction); interaction terms are tested before main effect terms. All significant terms and their lower-order counterparts are retained. The baseline covariate term and the treatment group variable are always kept in the final model.

RELATIVE SAMPLE SIZES NEEDED IN CUTOFF DESIGNS

The simulation study mentioned in section “Illustration: Cocaine Project” also showed that, everything else the same, more randomization resulted in lower standard errors of the treatment effect estimate and therefore increased precision. It can be shown that the amount of this precision is completely determined by the multicollinearity or correlation (R) between the baseline assignment covariate and the treatment group variable as expressed by the Variance Inflation Factor:^[16]

$$VIF = \frac{1}{(1 - R^2)}.$$

Suppose that there is a binary treatment group variable and a normally distributed baseline covariate. Table 1 provides the correlation between these two variables (R) and

the accompanying variance inflation factor (VIF) in symmetric cutoff designs with varying amounts of randomization and with 50% of the subjects within the interval assigned randomly to either treatment. The VIF can be interpreted as the design effect of how many more subjects are need in a given cutoff design relative to the completely randomized design in order to achieve the same level of statistical power, everything else the same.

Table 1 shows that, to achieve the same level of statistical power as the RE design, 2.75 times more subjects are needed in a RD design; 2.48 times more subjects are needed in a RD-RE design with 20% of all subjects randomized (i.e., 20% randomization); 1.96 times more subjects are needed in a RD-RE design with 40% randomization; 1.46 times more subjects are needed in a RD-RE design with 60% randomization; and 1.14 times more subjects are needed in a RD-RE design with 80% randomization. Derivations for the efficiency of such a cutoff design using an analogous approach, which gives essentially the same results, are published elsewhere.^[25]

SOME ADDITIONAL RESEARCH

Cutoff designs are certainly not without limitations. As mentioned earlier, an unbiased estimate of treatment effect requires that the functional relationship between outcome and baseline covariate be correctly modeled. Finkelstein et al.^[20,21] proposed a mathematical and statistical foundation, illustrated with examples, for how to analyze the RD design and to draw valid statistical conclusions about treatment efficacy. The authors discussed and illustrated their empirical Bayes methodology, which they mention can be used in a variety of circumstances, as a way to overcome restrictive assumptions about the functional form between outcome and baseline covariate. In other research, Hahn et al.^[26] have proposed a way of non-parametrically estimating treatment effects and offered an interpretation of the Wald estimator as an estimator of effect.

Table 1 Correlations and Variance Inflation Factors of Designs with Varying Amounts of Randomization

Percentage of all subjects within the interval of randomization	Correlation coefficient ^a	Variance inflation factor
0 (Regression-Discontinuity Design)	0.79	2.75
20	0.77	2.48
40	0.70	1.96
60	0.56	1.46
80	0.35	1.14
100 (Randomized Design)	0.00	1.00

^aExpected correlation between a binary treatment variable and normally distributed baseline covariate.

Another reservation about cutoff designs is that they preclude any serious attempt at complete blinding of treatment, making them similar to non-randomized designs in this regard. A further drawback of cutoff designs is they are less efficient (precise) than completely randomized designs in terms of their estimates of treatment effects. According to Senn,^[27] the considerable excess of patients treated on the inferior treatment in cutoff designs (especially the RD design) relative to the RE design is likely to undermine the ethical argument that favors cutoff designs. Although it is also true that more patients will receive the superior treatment in cutoff designs, regardless of which treatment it is, researchers are urged to consider Senn's position^[27] before abandoning randomization as a perceived ethical problem in a clinical trial.

Another variation of the RD design is the clustered RD design where groups (rather than individuals) are assigned to an intervention. The clustered RD design was the primary design to evaluate the federal education program prescribed in the No Child Left Behind Act of 2001. Schochet^[28] examined statistical power under clustered RD designs (without randomization) using techniques from the causal inference and hierarchical linear modeling literature. The main conclusion is that three to four times larger samples are typically required under the clustered RD design than the clustered RE design to achieve estimates of effect with the same level of precision.

Published studies using the RD design have focused primarily on linear regression applied to a categorical indicator and an interval-level response. Berk and de Leeuw^[29] formalized a generalization of the usual RD design to a wider range of situations. They focused on the use of a categorical treatment and response variables, but considered the more general case of any regression relationship. In addition, a resampling sensitivity analysis was shown as a way to address the credibility of the assumed assignment process. The broader formulation is applied to an evaluation of California's inmate classification system, which is used to allocate prisoners to different kinds of confinement.

CONCLUSIONS

Randomization should be employed whenever possible. Cutoff designs should not replace the completely randomized design in the majority of circumstances, usually involving a drug intervention, when no appreciable logistical barriers preclude all subjects from being randomized to interventions. Cutoff designs are an alternative design when circumstances in health services research or outcomes research warrant that randomization of all subjects cannot be undertaken, for whatever reason. Cutoff designs are much more likely to be relevant and appropriate in studies on program evaluation that involve educational or behavioral interventions, such as in disease management programs where randomization is not feasible ethically

or logistically for the entire sample,^[30] than in traditional Phase III studies on drug interventions, but cutoff designs may have some potential in Phase II therapeutic trials as well. When compared with non-randomized designs, the RD design (a cutoff design with no randomization) is an attractive alternative. When some subjects can be randomized, coupling the RD design with the RE design is even a more attractive alternative than the RD design.^[22–24,31]

Data Mining and Biopharmaceutical Research

Patricia B. Cerrito

University of Louisville, Louisville, Kentucky, U.S.A.

Abstract

In this entry, an overview will be given of the data-mining process and categories, including five data-mining methods: link analysis, kernel density estimation, text analysis, genetic programming, and artificial neural networks.

INTRODUCTION

Outcomes research requires routine data collection and the examination of information. Physicians should have a prominent role in decisions involving data collection, storage, and retrieval. However, physicians still have difficulty in adequately retrieving relevant medical information,^[1,2] and they require training to become proficient in this process.^[3] Methods that aid the physician in retrieving information need to be developed and disseminated to encourage evidence-based medicine.^[4] Improvement in information-retrieval tools is still needed,^[5–7] and data collection is still an important issue independent of data analysis.^[8–10] The collected clinical data require the use of data-mining tools to analyze the information.^[11–13] Data-mining techniques are ideal when data are collected in large databases.^[14–16]

Here an overview will be given of the data-mining process and categories, including five data-mining methods: link analysis, kernel density estimation, text analysis, genetic programming, and artificial neural networks. The application of these data-mining tools to clinical research will be illustrated by an analysis of MedPar data, a study of heparin dosing practices by two physicians, a quality-of-life analysis, and a study of polypharmacy. The examples will demonstrate the potential of the data-mining tools to find relevant information from clinical data.

THE DATA-MINING PROCESS

Data-mining tools come in three general categories:^[17] query-and-reporting tools, multidimensional analysis tools, and intelligent agents. Query-and-reporting tools include all the traditional statistical methods. They require close interaction between the investigator and the data in a specialized database or spreadsheet. Multidimensional analysis tools include the recently developed artificial neural networks and the Bayesian decision trees and require relatively structured data are structured by field and

observation. Text tends to be unstructured with sentences, phrases, and codes. Text uses more loosely defined terminology with different terms to define relatively the same concept, and similar terms with different meanings. The intelligent agents can investigate unstructured data and are the tools used to examine texts. These three categories of data-mining tools can be used in sequence to solve problems.

The process of data mining includes the following steps:^[18]

- Developing an understanding of the application domain, the relevant prior knowledge, and the goals of the end user.
- Creating a target data set, selecting a data set, or focusing on a subset of variables or data samples on which discovery is to be performed while considering the homogeneity of the data, change over time, and sampling strategy.
- Data cleaning and preprocessing, which includes removing noise and outliers and deciding on strategies for handling missing data.
- Data reduction and transformation, finding useful features to represent the data, depending on the goal of the task by using dimensionality reduction or transformation methods. In other words, the data need to be transformed into more useful forms from the original.
- Choosing the data-mining task by deciding whether the goal is classification, regression, clustering, summarization, or modeling.
- Data mining, performing the actual analysis, is automated and most often done using computer software.
- Evaluating output by determining what is actually knowledge and what is “fool’s gold.” Knowledge must be filtered from other outputs by using statistical checks, visualization, or expertise.
- Incorporating knowledge into the performance system and resolving potential conflicts with previously extracted knowledge.

DATA-MINING METHODS

There are many effective methods of data mining that are rarely used in medical studies:

- Link analysis (0 papers found).
- Kernel density estimation (5 papers found).^[19–23]
- Rule induction (7 papers found).
- Text analysis (15 papers found).^[24–25]
- Genetic programming (19 papers found).^[26–28]
- Artificial neural networks (909 papers found).^[29–31]

Note that only artificial neural networks are used with any regularity in medical studies. However, each method can be used to provide substantial information about drug actions and adverse events in clinical data. Image processing uses artificial neural networks. Many of the papers found dealt with the use of neural networks to automate the process of reading images that are recorded digitally.

Link Analysis

Link analysis explores the associations between large numbers of objects of different types.^[32] One of the principal uses of link analysis in medical research is to link primary effects to secondary effects. Link analysis is also a way to examine the adverse effects of medications during postmarketing surveillance. In particular, link analysis can determine whether a particular adverse event can be linked to just one medication or to a combination of medications. Further, link analysis can examine specific patient characteristics to determine whether they might correlate to both the adverse event and to the medication.

Recently developed software can examine thousands of objects and links simultaneously. For example, link analysis was applied to Medpar data, data that each hospital is required to report to the federal government for all Medicare patients. For a fee, the Medpar data are publicly available. Secondary diagnoses were linked based on a common primary diagnosis (Fig. 1) (SAS Institute, Cary, NC). For the Medpar data, it was possible to label up to nine different secondary diagnoses. The links were among the secondary DRG codes, limited to the most prominent 100 links. Code 4111 = intermediate coronary (the largest square in the diagram) was the code used most often in the patient data set. One of the strongest connections was to secondary code #4 = 4019 (hypertension).

Kernel Density Estimation

When the data are not normally distributed, it is possible to estimate the population distribution by using the kernel density estimate,^[33,34] defined by

$$f(x) = \frac{1}{nh_n} \sum_{j=1}^n K\left(\frac{x - X_j}{h_n}\right)$$

Fig. 1 Diagram of a link analysis

where K is a known density function, n is the sample size, and h_n is a parameter depending upon n and the population density function. It is known that the choice of K is unimportant to the relative efficiency of the estimator. There are several algorithms used to optimize the choice of h_n . The choice of bandwidth in this example is given by solving the fixed-point equation:

$$h_n = \left[\frac{R(\varphi)}{nR(\hat{f}_{g(h)}) \left(\int x^2 \varphi(x) dx \right)^2} \right]^{1/5}$$

The fixed-point equation can be used to accurately estimate drug levels over time, or the actual time between monitoring drug levels.

Although these techniques are still relatively new and inconstant development, they are not generally used in applications.^[35,36] Nevertheless, some studies have used the technique of kernel density estimation to classify data.^[19,22] Kernel density estimation provides more information than the standard statistical techniques, which rely on averages. Consider Fig. 2 where it is clear that one physician

Fig. 2 Heparin dose by physician

typically uses a higher dose of heparin per unit weight than does a second physician. Although a standard analysis of variance would show that the two physicians are different, the graph demonstrates the extent of the difference. A conference with Physician B resulted in a change in practice to lower heparin-dosing habits.

Rule Induction

Rule induction takes the form IF condition THEN conclusion. For a rule under consideration, the following sets of records are defined:

A = {r|condition of rule is satisfied (i.e., the rule classifies a record)}.

B = {r|conclusion of rule is satisfied (e.g., the patient has died)}.

C = {condition and conclusion of rule are satisfied (i.e., the rule correctly classifies a record)}.

If a,b,c, respectively, are the number of records in the sets A,B,C, then the accuracy is equal to c/a and the sensitivity is equal to c/b . The objective then is to produce rules that maximize c and minimize the differences $a - c$ and $b - c$. The basic format of rule induction is modified to account for missing values, and multiple nodes of IF-THEN rules are added until all patient records are classified.

It is also possible to examine the issue of which secondary factors are associated with higher predicted risk using rule induction with the Medpar data. Different levels of complexity in the model can be used to increase the level of accuracy in predictions. In this way, it is possible to find the risk factors that need to be the focus to improve hospital ranking. This can be done by increasing the proportion of patients with the needed risk factors. The major leaves of the Bayesian tree were used to predict the risk of severity. Using the first five recorded secondary diagnoses as input variables, the results are summarized in the table below:

0389 20280 25002 2763 2765 2866 2874 29570 3441 34510 3688 40391
41011 41091 42090 4230 4241 42610 42653 4270 42741 4275 43491 436
4589 4822 4824 5070 5185 51881 51882 53540 53541 55320 5715 5750
5770 5789 5845 5849 585 7070 78009 78551 78791 78830 7885 7889
7991 99701 99702 9973 9975 9983 99859 V420

Node	Number of patients	Classified in risk category 1-3 (%)	Classified in risk category 4 (%)
2	137	18.98	81.02
4	84	32.14	67.86
6	31	22.58	77.42
7	1779	98.20	1.80

Node 2 is identified solely based upon the secondary diagnoses in column 5.

TEXT ANALYSIS

Text analysis examines unstructured texts for meaningful information. Using standard clinical data that are routinely collected, often in paper format, text analysis can be used to find standardized “natural language” pieces of information. Once the text has been organized, statistical methods for clustering and classification can be used. It is possible, for example, to construct patient profiles based upon the clustering of secondary diagnoses. The use of natural language allows for equivalent phrasing to classify patients based on comorbidities. For example, a Medpar database containing 4814 Medicare patients was examined using text analysis on the fields of secondary diagnoses given a specific primary diagnosis. The resulting text analysis was grouped into 10 separate clusters that had the following numbers of patients (Table 1) (SAS Institute, Cary, NC). The top three clusters were identified by DRG codes (Table 2).

Cluster 4 is focused primarily on mental problems, including drug use; cluster 9 is focused on urinary and digestive problems; and cluster 7 is focused on anemia, fluid depletion, and chronic obstructive bronchitis.

Genetic Programming

Genetic programming extracts ideas from the growth and evolution of living creatures and applies them to practical problems. It has been used occasionally to facilitate difficult diagnoses.^[27,28] The basic unit of work in genetic programming is the expression. An expression is a dendrite structure built from a predetermined alphabet of basic program elements. Program elements include simple arithmetic functions, Boolean operators, and terminal symbols such as random numbers, constants, or problem data. Genetic programming is used by building an initial population of random expressions, each of which attempts to solve the problem, usually in a series of object cases or

Table 1 Number of Patients in Each Cluster Identified by Secondary Diagnoses

Cluster	Patient total
1	75
2	30
3	19
4	732
5	68
6	25
7	1612
8	57
9	905
10	73

Table 2 Most Reported Secondary Diagnoses Per Cluster

Rank appearance	Cluster 4	Cluster 7	Cluster 9
1	2721 (lipoid metabolism disorder)	2851 (acute posthemorrhagic anemia)	43330 (occlusion and stenosis)
2	V1048 (history, malignant neoplasm)	2767 (fluid disorder)	5997 (hematuria)
3	V4502 (cardiac device in situ)	3963 (mitral and aortic valves, rheumatic fever)	9975 (urinary surgical complication)
4	V1301 (history of other diseases)	2765 (volume depletion)	2749 (unspecified gout)
5	V5861 (long-term drug use)	49120 (chronic obstructive bronchitis)	4401 (renal artery atherosclerosis)
6	7802 (syncope, collapse)	4589 (hypotension)	4270 (paroxysmal supraventricular tachycardia)
7	311 (depressive disorder)	4260 (complete atrioventricular block)	44020 (native arteries atherosclerosis)
8	V145 (history of allergy)	4275 (cardiac arrest)	53390 (peptic ulcer)
9	4242 (other disease, endocardium)	78039 (convulsions)	V103 (history of malignant neoplasm)
10	V1271 (history of certain other diseases)	49121 (chronic obstructive bronchitis)	42613 (atrioventricular block)

trials. Some expressions are more successful than others in solving various cases.

Genetic operations of selection, mutation, and reproduction are applied to the initial expressions, leading to the construction of a new generation of expressions that generally shows improved performance over the initial population. The expressions in each succeeding generation continue to attempt to establish solutions and breed high-performing expressions. Each succeeding generation builds on the best efforts of the last. In every generation, the expressions are ranked according to their ability to make a prediction. The ablest expression is designated the “best of generation.” Eventually, the problem is solved by the emergence of an expression with the highest possible predictive rate. The best of the final generation is designated the “best of run” and becomes the final solution.

Artificial Neural Networks

A neural network is a connected network of processing elements called neurons. A neuron occupies the computational ground between simple on/off memory bits and complex data processing units. It receives input values, represented typically as real numbers, on multiple input lines and computes a weighted sum based on these values. The neuron then uses the sum to compute an activation or threshold value. The activation value is passed to an output line that may in turn be passed as input to another neuron or may represent the final output of the network. A group of neurons, arranged in interconnected layers with judiciously chosen interconnection weights, can perform useful computations. Some neurons accept input

from the environment, others perform internal (hidden) calculations, and still others present the final result of the network's cogitation (Fig. 3).

Neural networks have several advantages. They are able to accommodate and represent a range of data types (continuous, binary, and categorical values) and they can be made relatively insensitive to missing data. They are ideal for classification studies and consistently outperform both logistic regression and discriminant analysis (both parametric and nonparametric). Neural networks have been used to examine heart function. They excel in classification, far exceeding the predictive ability of the more standard logistic regression.^[20,21] Consider an analysis comparing the quality of life for patients with two competing treatments (Table 3). The question to be answered was whether patients who had a lower quality of life routinely took the experimental treatment. Based upon the results of the quality-of-life scale, the model attempted to identify whether the patient was taking the experimental treatment, or was in the control group. Overall, the accuracy

Fig. 3 Diagram of a neutral network

Table 3 Prediction of Treatment Group Based on Quality of Life Responses

Value	Training set neural network	Validation set neural network	Training set genetic programming	Validation set genetic programming
Sensitivity (%)	72	63	59	53
Specificity (%)	79	79	96	84
False-negative rate (%)	3.5	9	23	21
False-positive rate (%)	7	62	7	38
Accuracy (%)	76	72	81	74

of prediction was equal to 70% using logistic regression compared to 72% for neural network analysis and 74% for genetic programming.

Logistic regression, without splitting the data into training and validation sets, achieved sensitivity of 74% and a specificity of 51%, whereas the neural network achieved a sensitivity of 63% on the validation set (72% on the training set) but a 79% specificity, indicating a more accurate model.

CASE STUDY: DATA MINING AND POLYPHARMACY

Given many possible combinations of drugs and the high incidence of polypharmacy, data mining is particularly useful in examining the problem of polypharmacy, defined as when a patient takes more medications than are needed and often suffers from drug interactions.^[37] Many people are taking multiple medications for comorbid problems. It becomes difficult if not impossible to examine the problem of adverse effects without the investigation of drug interactions and the complex combinations of drugs. Data-mining techniques were initially designed to deal with issues of complexity; however, data-mining techniques need to be incorporated into investigations of polypharmacy and drug interactions. Antipsychotic prescribing was examined from March 1 to May 31, 2000. There were 26 nursing facilities serviced and 270 physicians treating patients. The data were collected by the consulting pharmacist who did not have access to any identifying information. The physicians were identified by number only, and only the total number of prescriptions for each physician identification number was made available to the investigator.

The number of prescriptions issued is given in Table 4. Of 2876 patients in 26 facilities, 520 patients (18%) were prescribed antipsychotics. For the 520 patients, 34 (6%) were prescribed two different antipsychotics. It is only when looking at global prescribing practices that abuses can be uncovered, and improved.

CONCLUSION

The techniques of data mining—link analysis, kernel density estimation, rule induction, text analysis, genetic programming, and artificial neural networks—can greatly

Table 4 Physician Prescribing Patterns

Drug	Number of prescriptions
Chlorpromazine	7
Clozapine	1
Fluphenazine	4
Haloperidol	49
Mesoridazine	4
Molindone	2
Olanzapine	62
Perphenazine	8
Prochlorperazine	14
Quetiapine	30
Risperidone	97
Thioridazine	28
Thiothixene	7
Trifluoperazine	1
Triflupromazine	1

facilitate the study of patient outcomes, particularly when it comes to investigating quality-of-life issues and polypharmacy. The techniques were designed to deal with large databases of clinical information routinely collected in the course of practice. The text mining techniques can also deal with the collection of paper in each patient chart. Therefore, surveillance of drugs and drug interactions can be much facilitated by the use of these techniques.

Data Monitoring Committees (DMC)

Jay Herson, PhD

Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland, U.S.A.

Abstract

This article describes the objectives, membership, creation, and organization of a data monitoring committee in industry-sponsored clinical trials. Both safety and efficacy monitoring are included as are a description of the charter, conflicts of interest, clinical, regulatory and statistical issues/methods, multiregional trials, use of MedDRA and standard MedDRA queries, sources of bias, and types and methods of decisions made by data monitoring committees including interim analyses for superiority and futility. The article concludes with emerging issues including adaptive designs, novel designs in oncology, centralized risk-based monitoring, fraud detection, and training of committee members.

Keywords: Adaptive designs; Charter; Clinical trials; Data monitoring committee; Futility analysis; Interim analysis; MedDRA; Patient safety; Safety analysis.

INTRODUCTION

A data monitoring committee (DMC) in an industry-sponsored clinical trial is an independent panel charged with preserving the integrity of the trial by protecting patient safety. The DMC must also ensure that interim analyses of superiority or futility of an experimental agent are performed correctly. If there needed to be only one word to describe the DMC's responsibility, it would be *stewardship*. The DMC might be thought of as the board of directors of the trial and the sponsor study team as the officers of the trial. We will see later that there are other types of independent committees that also interact with the sponsor on operational issues.

We will use the terms “treatment” or “drug” in various places, but these terms could apply easily to pharmaceuticals, biologics, or medical devices. The term “pharma” could apply to trial sponsors in either of the three previously mentioned industries. The terms “study drug” and “study treatment” denote either the experimental treatment or the control group treatment.

History

In the late 1960s, the National Institutes of Health (NIH) concerned that clinical trials under their sponsorship should have some form of independent review and felt that there was a need for some definition of best practices. The National Heart Institute, as it was known at the time, commissioned what has become known as the “Greenberg Report” as a way of beginning to deal with

these issues. The report was completed in May 1967 but not published until 1988.^[1]

The 1970s saw a considerable growth in pharmaceutical industry clinical trials. Although the NIH-sponsored trials were research oriented using already approved drugs, the pharmaceutical industry trials were more development or product oriented. They were designed to generate efficacy and safety data for submission to a regulatory agency for approval of an experimental treatment. One of the first DMCs in a pharmaceutical industry trial was the cimetidine stress ulcer clinical trial in 1988–1989.^[2] This trial was conducted in intensive care units and compared cimetidine to placebo for prophylaxis of upper gastrointestinal bleeding due to stress.^[3] The sponsor decided that an independent committee was needed to review the bleeding data in a masked (i.e., blinded to treatment assignment) manner rather than the sponsor so as to minimize the perception of bias. Because these were patients treated in emergency rooms, the DMC was also needed to determine whether deaths on treatment were disease related. This was the beginning of the DMC era for industry-sponsored trials.

As DMCs began to appear in pharmaceutical industry trials, regulatory agencies such as FDA and the International Conference on Harmonisation created guidance documents.^[4–7] These documents mentioned the advisability of independent review of safety and efficacy data. Ellenberg et al.^[8] and DeMets et al.^[9] wrote the first two books that dealt specifically with DMCs. These books drew on the authors' experience in NIH-sponsored trials. Herson's first and second editions deal with the evolving best practices for DMCs in the pharmaceutical industry.^[10,11]

Other Vehicles for Patient Protection

DMCs are not the only source of protection of patient safety. Each clinical site comes under the auspices of an Institutional Review Board (IRB), in some countries called an Ethics Committee, which reviews protocols and their amendments and receives periodic safety reports. Each sponsor has an internal masked safety review system, and some sponsors even have internal safety review committees. Some large research hospitals have their own internal DMC-like committees that review safety on ongoing trials regardless of sponsorship.

The FDA recently issued a guidance calling for a Safety Assessment Committees (SAC).^[12] This is a term likely to be confused with DMCs. The SAC, consisting of both internal and external experts in medicine, biostatistics, and epidemiology, has broader responsibilities than the DMC. The SAC will review data from a specific clinical trial but also from other trials on the same or similar drugs, epidemiologic studies, insurance claims data, and so on in order to get an overall impression of the safety profile of the experimental treatment. SAC implementation is not clear at this time and may be an activity more likely to be supported by only the largest firms in the industry.

Place of DMCs in the Development Cycle

DMCs, as described in this article, have become commonplace in Phase III/confirmatory trials. Earlier phase clinical trials (Phases I and II) might have some form of independent review but would not usually be as independent of the sponsor as the DMC for a confirmatory trial. Several papers in the literature give guidance on how independent review can be incorporated into early-phase trials if sponsors want to establish this type of input.^[13,14]

A current concern among regulatory agencies is the occasional blurring of lines between development phases. A recently approved oncology drug began as a Phase I trial, but, as favorable results were observed, more patients were added. Eventually, there were over 1200 patients on this protocol, and the 179 patients with advanced melanoma were considered sufficient for FDA approval.^[15] There was no DMC involvement.

Sponsor Size

We are assuming that the sponsor in the trials we discuss is a company—pharmaceutical, biotechnology, or medical device. The size of the sponsor drives many activities of the DMC.

Herson^[11] defines *Big Pharma* as a public company with many products on the market with a goal in the current trial to expand its product line, *Middle Pharma* as a public company with a few products on the market with a goal of expanding the product line and forming corporate partnerships or mergers with Big Pharma, and *Infant Pharma* as a

company that could be public but likely surviving on venture capital investments, no products on the market with a goal of showing positive progress of a successful product. Big Pharma and Middle Pharma have DMC procedures in place. This is usually not the case for Infant Pharma, and, indeed, procedures are often written when the trial is in progress and often at the advice of experienced DMC members. Infant Pharma is much more vulnerable to DMC decisions than Big Pharma or Middle Pharma, and thus, there is increased tension in the DMC–sponsor relationship in Infant Pharma trials.

ORGANIZATION OF A SAFETY MONITORING PROGRAM IN CONFIRMATORY TRIALS

Most of the data collected in confirmatory trials are safety related. As we will see later, DMCs are involved in safety assessment at and between periodic meetings but with efficacy analysis only at specified interim analyses if such decision points are specified in the protocol. In this section, we will describe how the DMC fits into the safety monitoring process.

Members of the Safety Monitoring Team

The members of the safety monitoring team in addition to the DMC will be the sponsor staff headed by the Sponsor Representative, the sponsor employee in charge of the clinical trial, the Data Analysis Center (DAC), and the IRB.

The DAC will prepare the tables, listings, and graphs for DMC review. The DAC representative will be a biostatistician unmasked to treatment assignment. The DAC biostatistician will attend DMC meetings. The DAC might be a division of the sponsor with an effective firewall between this DAC and the sponsor staff. However, it is considered better practice for the DAC to be an independent contract research organization (CRO) retained by the sponsor for this purpose.

The IRB or Ethics Committee exists at every institution participating in the trial. The IRB protects the patients of their own institution by inspecting the trial protocol, informed consent, investigators brochure, and so on. They will review safety data within their institution and only trial-wide safety data on adverse events that are serious, treatment related, and unexpected. All IRB members are masked to treatment assignment.

There are two other committees that may be involved in clinical trials. The *endpoint adjudication committee* will be masked and make decisions on efficacy endpoints that require interpretation. This will often entail reviewing images, EKGs, hematology reports, and so on. The *steering committee* advises the sponsor on the conduct of the trial. Although DMCs exist in virtually all confirmatory trials, the endpoint adjudication and steering committees exist in only a few trials.

DMC Creation

It is the sponsor's responsibility to recruit DMC members. A typical industry DMC consists of three members—two physicians and one biostatistician. These three are voting members and are generally recruited from academia and government. The two physician members are generally experts in the indication under investigation, e.g., oncologists, cardiologists, and rheumatologists. If certain adverse events are anticipated, such as cardiotoxicity in an oncology trial, a cardiologist might be added to the DMC. For some adverse event types, it might be advisable to enroll ad hoc consultants who would not be the members of the DMC but could advise the DMC when necessary. It is considered good practice not to disclose the names of DMC members to investigators or the public until after the trial is completed.

Conflicts of Interest

Each sponsor should have standard operating procedures (SOPs) for DMC creation and operations. These SOPs must define what would constitute a conflict of interest for a DMC member. The criteria would usually consist of consulting for or serving on a DMC for a competing company working on therapeutics for the same indication as the trial addresses. There would also be limits as to how much a DMC member could earn annually from the sponsor since the DMC member could also be advising the sponsor in other ways. Indeed if a DMC member received high compensation from the sponsor, the independence of this member would come under question. As a result, DMC members receive modest compensation. DMC service should always be seen as service to science and not a lucrative consulting opportunity. DMC members will be asked at every meeting if there have been any changes that might constitute a conflict of interest since the previous meeting.

Liability and Indemnification

There must be clearly a way to protect DMC members against liabilities that might occur in the trial for which they are not responsible. It is considered the best practice for the sponsors to include an indemnification clause in DMC member contracts. Although some contracts call for mutual indemnification, it makes little sense for DMC members to indemnify the sponsor. DeMets et al.^[16] provide useful guidelines for what should be included in an indemnification clause. Fleming et al.^[17] discuss the many issues involved in sponsor indemnification of DMC members.

MEETINGS

DMC Charter

The DMC Charter issued by the sponsor, with possible modifications by the DMC members, governs all meetings

and operations of the DMC. The Charter will specify DMC membership and responsibilities and conflict of interest policy. Additional items would include whom the DMC reports to, serious adverse event (SAE) data flow, DAC responsibilities, meeting minutes, and retention policy. Eventually, the DMC, sponsor, and DAC will agree on a Data Review Plan (DRP)—templates of tables, listings, and graphs to be reviewed at DMC meetings. The final version of this plan will be appended to and considered part of the Charter.

Orientation Meeting

Before the trial begins, the sponsor staff will convene a kickoff meeting with the DMC members and the DAC biostatistician. At this meeting, the sponsor will present the Charter and possibly preliminary drafts of the DRP. The orientation meeting is often face to face.

The sponsor will have already chosen the DMC Chair, and this person will cochair the orientation meeting, but the DMC Chair will run all subsequent meetings. The DMC members will select a recording secretary among themselves. This person will record the minutes of closed meetings.

Masking policy is an important component of the orientation meeting. The sponsor staff will certainly be masked to treatment assignment during the trial. DMC members will be either unmasked or partially unmasked. In the latter case, the treatments are referred to only as A and B throughout the trial. At any meeting after the orientation meeting, the DMC members may ask the DAC biostatistician to reveal the identity of A and B. This is done because many DMC members do not feel that they can do their job properly without knowing treatment assignment. If they remain only partially unmasked, they will inevitably try to guess the identity of A and B as adverse event reports accumulate. However, if they guess wrong, this could adversely affect decision-making throughout the trial. If DMC members decide to unmask, they do not have to inform the sponsor of this decision.

At some point, DMC members might have a safety concern that they would like to discuss with the sponsor. They cannot discuss this directly with the sponsor team because it might unmask them. Big Pharma and Middle Pharma sponsors will usually have a pharmacovigilance (PV) group separated from the sponsor team. Infant Pharma would not have such a group so the orientation meeting is a good time for the Infant Pharma sponsor to identify an independent consultant who could act as a PV. The PV would take on the task deciding what should be done and what information should be conveyed to the study team. It is good practice for all documents that circulate during a trial to put an asterisk after those persons who are known to be unmasked so as to minimize accidental unmasking.

The DMC members will also be asked to review the investigator brochure and the protocol at the orientation

meeting. The DMC is free to recommend the changes to the protocol such as adding or changing the frequency of stress echocardiography, modifying eligibility requirements, or inquiring about plans to ensure enrollment of minorities. Although each institution participating in the trial and its IRB has the responsibility to prepare its own informed consent agreements, the DMC members may also review and comment on the trial-specific expected adverse event information the sponsor has sent to the institutions for inclusion in their informed consent.

Agreements will also be made of the SAE data flow—72 h reporting adverse events and periodic reports of newly occurring adverse events. Usually, these reports will only go to the DMC Chair and he/she will alert other members as needed.

As noted previously, it is the Charter and DRP that will guide DMC operations. The sponsor will have already planned a statistical analysis plan and perhaps have followed the SPERT Committee guidelines^[18] and prepared a Program Safety Analysis Plan, but these plans refer to planned interim and final analyses of efficacy and safety. The DRP is a subset of these documents relating to the ongoing data review of the DMC. Plans would be made at the orientation meeting for sponsor–DMC–DAC collaboration to complete the DRP.

Herson^[11] provides an appendix with a complete list of potential DMC responsibilities and DRP contents.

Data Review Meetings

The first data review meeting will be scheduled after X patients have received Y cycles of treatment or after Z months from trial commencement, depending on which comes first. X , Y , and Z are the numbers to be specified based on the specifics of a trial protocol. This policy ensures that early-enrolled patients are not unduly at risk for lack of data review because enrollment is slow. There are usually two to three data review meetings each year, but the ultimate frequency depends on the specific clinical trial. Most data review meetings are by teleconference/WebEx.

The data review meeting has an open and a closed session. The sponsor team, DMC members, and DAC biostatistician attend the open session. The sponsor team will report the study progress and compare the projected and actual enrollment explaining the discrepancy, if there is one. The data cutoff for data compiled for this meeting will be announced. It may be 6–8 weeks prior to the meeting due to the need for data cleaning. A complete safety report will be presented with all treatment groups combined because the sponsor staff must remain masked. The sponsor staff will report on pending action items from previous meetings. This usually entails tasks with enrollment by center, noncompliance, and so on. Herson^[11] presents a sample agenda for an open session.

Only the voting DMC members and the nonvoting DAC biostatistician attend the closed session. The DMC members will go over the tables, listings, and graphs prepared by the DAC. They will follow up on previous safety issues and seek new concerns. If a planned interim analysis of efficacy is due at this meeting, this will be done as well. The precise methods to be used for these activities will be reported later in this article.

At the conclusion of the open session, the DMC Chair will report to the sponsor representative whether the trial can continue with or without protocol amendments.

CLINICAL ISSUES

Goals of Safety Analysis

The safety analyses undertaken by the DMC seek to separate the signal from noise, i.e., to distinguish adverse events that are part of the disease process, or preexisting or concurrent conditions, and those related to concomitant medication from those that are related to study treatment. We call the latter *treatment-emergent adverse events* but will use the shortened term *adverse events*. The latter can be defined as any unfavorable and unintended sign (e.g., including an abnormal laboratory finding), symptom or disease temporally associated with the use of a treatment, or whether considered related to this intervention.

A SAE is any untoward medical occurrence that, at any dose, results in death, is life threatening, requires inpatient hospitalization or prolongation of existing hospitalization, and results in disability/incapacity. This is a clinical/regulatory term, and the various regulatory agencies have expedited reporting requirements for SAEs. Sponsors and DMC members agree on a SAE data flow at their orientation meeting.

A purely clinical term that must not be confused with SAE is the *severe adverse event*. The latter refers to the intensity of the event but not necessarily the seriousness. A severe headache would usually not qualify as serious, but a mild case of dehydration would be considered a SAE. There are various ways to define the severity of adverse events. We will provide a brief description later.

Another category of adverse event is the serious unexpected suspected adverse reaction (SUSAR). This new definition comes from an FDA guidance communication to industry on safety reports,^[19] which has become known as the “Final Rule.” The SUSAR is an adverse event that the sponsor, not necessarily the DMC, believes is causally related to the experimental treatment. Closely related is the adverse events of special interest (AESI). The sponsor may prepare an AESI list prior to the beginning of the trial, but the DMC will suggest additions to both the SUSAR and the AESI list as the trial progresses.

Safety Data

The safety data originate on case report forms and are transmitted by the investigator sites to the sponsor or CRO where data cleaning takes place. Eventually, the coding of the adverse events will be through an adverse event dictionary such as *Medical Dictionary for Regulatory Activities (MedDRA)*.^[20] MedDRA is a hierarchical coding system beginning with a system organ class (SOC) and down to a preferred term for a condition within the SOC. Often there are many preferred terms within a SOC, and this contributes to the granularity of the SOC. DMCs must deal with granularity because similar adverse events might be spread over several preferred terms and, thus, clouding analysis. We will return to the issue of granularity later, but it is encouraging to report that progress has been made recently in the definition of *standardized MedDRA queries (SMQs)*. The SMQs were developed by the MedDRA organization using the advice of expert committees. An example of an SMQ would be major adverse cardiac event (MACE), which combines MedDRA terms such as “all-cause mortality,” “myocardial infarct,” and “target vessel revascularization.”^[21] In addition, some sponsors have created proprietary SMQs, and the DMC members often suggest additional SMQs as they review data.

Adverse event severity must also be coded. The common severity levels are “mild,” “moderate,” “severe,” or “life threatening.” Adverse events are coded into these categories using various dictionaries like *MedDRA* or *Common Terminology Criteria for Adverse Events*,^[22] the latter being the preferred dictionary for oncology trials.

Another important source of safety data for DMCs are the narratives. These are written descriptions of the adverse events prepared by masked members of the sponsor’s PV staff. The narratives are compiled after reviewing all information available including interviews with the investigator. The content of the narratives is often discussed during DMC closed sessions. Often the narratives are delayed because some text must be translated to English before the PV staff can prepare the narrative. A common format for narratives was developed by the Council for International Organizations of Medical Science and is often referred to as the CIOMS form.^[23]

Clinical Issues in Multiregional (Global) Trials

In the past few decades, there has been a considerable increase in conducting clinical trials on a global scale. Inclusion of India, China, and Eastern European sites is now common. Binkowitz and Ibia review problems encountered in multiregional trials for efficacy endpoints.^[24] What follows is a review of issues encountered by DMCs with safety endpoints.

There are geographic patterns of genetic variation that may affect adverse reactions. Different cultures vary in their propensity to self-report adverse events. In some

state-run European health systems, physicians have a financial incentive to hospitalize patients who experience adverse events. These patients would not usually be hospitalized in other countries. Hospitalization qualifies as a SAE, and, thus, the SAE listing is a pool of “real” SAEs and those generated by a financial incentive. Similarly, some European countries require sponsors to unmask whenever a SAE is reported. This can introduce bias in conduct of the trial so most sponsors would just have the PV group unmask rather than the study team.

If surgery is involved in the clinical trial, it can become problematic when surgical and anti-infective practices vary among countries. Similarly, standard of care is often a control group treatment in clinical trials, and the standard may vary among regions. Even when an already approved drug is the control treatment (active control), different control treatments may need to be used in different regions because some active control candidates have not been approved or are not available because of cost in some regions.

Clearly, the issues described previously can differentially affect the incidence of adverse events seen by DMC members. Some DMCs will request physician consultants from the different regions to help with interpretation of data in multiregional trials. Herson^[11] presents a comprehensive description of safety issues faced by DMCs in multiregional trials.

STATISTICAL ISSUES

Goal of Statistical Analysis

The goal of safety analysis is to separate signal from noise, i.e., treatment-emergent adverse events that are related to study treatment rather than the disease process, or preexisting or concurrent conditions. DMC members will review tables, listings, and graphs prepared by the DAC and occasionally use statistical methods. Unlike efficacy analysis, safety analysis does not hinge on the statistical significance of a single endpoint. Indeed, there might be statistical significance in the difference in the incidence of mild transient headache between treatments, but the DMC members would likely not consider this of clinical significance. Similarly, there might be two cases of renal failure in the experimental treatment group and none in the control group. Although this difference might not be of statistical significance, DMC members would likely consider it of clinical significance. In this section, we will show the important ways that DMC members can use statistical methods.

Useful Data Displays

DMC members will see many useful displays in the open session where there is no distinction between treatment groups. This would include enrollment by center, ethnicity,

and stage of disease. These tables will indicate where patients are coming from and the underproductive sites, which may need attention. A graph of cumulative patient enrollment by month because trial commencement vs. projected enrollment is useful to indicate trial progress. At one time, the projected enrollment was usually presented as a straight line, but, more recently, computer simulations taking sponsor experience with investigator site start-up and time to steady-state enrollment generate the projections which are usually not linear.

In the closed session, the first useful graph is the cumulative distribution of patient exposure to study treatment by month. The Kaplan–Meier graphical method,^[24] to be described next, is useful for this display. The *Y*-axis is the number of patients, and the *X*-axis is the number of months after treatment start. The curves are monotonically increasing and show the cumulative number of patients still on therapy by treatment arm and month. If the curves diverge, it may be evidence of difference between treatments in toxicity incidence, disease progression or mortality.

Of course, the major source of closed session DMC deliberations is the adverse event tables. These tables come with the highly detailed MedDRA hierarchy and are supplemented by the SMQs discussed previously and by treatment group denoted A or B. Sponsors usually offer a table classified by investigator's judgment of relatedness to study treatment, but most DMCs ignore this table preferring the conservative approach to assuming all adverse events could be study treatment related. The first tables are usually for all adverse events, and then come tables for all SAEs and then tables for adverse events with severity moderate or higher. For each of these tables, DMC members will first look at the comparison of treatment groups in the first section consisting of all adverse event types combined and later explore the individual adverse event types. Early in the trial, there will be few safety signals because of low frequencies in most of the cells.

Statistical Description

In this section, it is assumed that the reader is already familiar with most of the common statistical methods described. Thus, we will not provide detailed formulas. A useful reference is the textbook by Rosner.^[25]

Data reduction begins with the incidence calculation. The incidence of any adverse event frequency is the frequency divided by the number of patients in the treatment group. This is the most common calculation used by DMCs, but more useful is the rate/100 patient-years of exposure. DACs currently always report the total sample size at the top of each treatment group column, but they should also report the number of patient-years of exposure. The latter is simply the sum of exposure time to study treatment converted to years. The rate per 100 patient-years is the frequency multiplied by 100 divided by the number of patient-years. For example, suppose the frequency of moderate or higher

nausea in the experimental treatment is 55 patients, and the total number of months of exposure of this treatment group is 912. We convert months to years $912/12 = 76$ years. The rate per 100 patient-years then is $55 \times 100/76 = 72.4$. We will see in Section "Hypothesis Testing" how this experimental treatment rate can be compared to that of the control group.

For adverse event types that the DMC feels need closer inspection or the declared AESI described in above, the DMC might request a Kaplan–Meier graph of time to the first occurrence of the event. The Kaplan–Meier life table method is usually used to compare two treatment groups, and we will see how in Section "Hypothesis Testing". The one-sample use of Kaplan–Meier generates the landmark estimate. If the DMC wants an estimate of the cumulative adverse event incidence at 12 months, it would be improper to divide by the number of patients still on the trial at 12 months, but the Kaplan–Meier 12-month estimate read from the Kaplan–Meier curve is the landmark estimate. It provides a 12-month incidence that includes the exposure times of all patients who began the trial including those no longer being followed in the trial.

Hypothesis Testing

Tables prepared by the DAC for DMC use in closed sessions generally have frequencies and incidences computed but not *p*-values for treatment comparisons. The DMC biostatistical member might look over the tables and compute the summary statistics and *p*-values of observed differences (computed by chi-square test or Fisher's exact test) as a way of calling potential differences to the attention of the physician members. Of course, these comparisons are not planned, and multiplicity issues might cloud the inference. In addition, we often do not find statistical significance in these comparisons because the sample sizes are too small to yield the power to detect a difference. These are all points that the biostatistical member should explain to the physician members. Calculations that might be made with or without associated *p*-values would be relative risk and odds ratios. The rate per 100 patient-years described previously follows the Poisson distribution, and the ratio of two rates is called the Poisson rate ratio. This is a useful method. Of course, the Kaplan–Meier table method can be used to compare the treatments corrected for exposure, and a log-rank test can be used for statistical significance. Herson^[11] illustrates all of these methods with numerical examples from a high-profile clinical trial. He also presents the likelihood and Bayesian methods although these are rarely used in DMC work.

BIAS AND PITFALLS IN INTERPRETATION

What Is Bias?

Piantadosi^[26] defines bias as a systematic (nonrandom) error in the estimate of a treatment difference, i.e., effects

other than the treatments themselves. DMC members are concerned with sources of bias that can create distorted treatment differences in safety. There are other pitfalls to interpretation that do not meet the precise definition of bias, but we will discuss them in this section as well.

Knowledge of Treatment Assignment

The sponsor staff should make every effort to avoid accidental unmasking to treatment assignment. The PV staff, or a designated consultant acting in this capacity, is a big help in shielding study staff from accidental unmasking. The DMC members themselves may have decided to unmask themselves, and many believe this is the only way the DMC can protect patient safety. There is no evidence that DMC unmasking has contributed serious bias to the DMC operations.

Reporting Bias

If investigators are unmasked or de facto unmasked because they can distinguish treatments by the adverse event footprints they leave, there might be an underreporting of adverse events in the active control group because investigators feel that the adverse event profile of the active control treatment is well known. Clearly, historical data on adverse event levels for the historical control are available for comparison. Fay et al.^[27] have developed a method to test the statistical significance of SAE incidence in a clinical trial compared to a historical control. This method may be useful to DMCs who suspect underreporting.

When a trial is terminated early due to treatment superiority or non-inferiority in efficacy, there may be incomplete follow-up on adverse events after the termination because investigators have moved on to other tasks. DMCs must insist on complete follow-up and not relinquish their responsibilities just because the trial has ended.

Adverse events may be collected in a spontaneous or solicited manner.^[28] In the former, the study merely asks a patient what side effects, if any, the patient has experienced since the last visit. For solicited adverse events, the nurse will go over a list of adverse events, which are either on the AESI list or on the ones that are often forgotten on underreported. The solicited route would reduce underreporting of these adverse event types. DMC members can advise the sponsor on which approach appears most appropriate for a given clinical trial.

Bias at the Analysis Level

There are several sources of bias that can creep in at the time of data analysis, and DMC members should be aware of these possibilities. When a clinical trial is terminated early due to efficacy, there may be lingering safety questions that cannot be answered because of small numbers of patients. If the sponsor is providing continuing treatment for experimental

patients and crossover treatment for control patients, the DMC should insist on the remaining intact to analyze the accumulating data for this and other safety issues.

The issue of granularity (numerous preferred terms for an organ class) has been introduced in Section “Clinical Issues.” There we saw that the SMQs such as MACE in cardiovascular disease are a big help. Still there are many diseases where safety signals may be coded across preferred terms and organ classes. For example, congestive heart failure can be missed if adverse event reports are spread across terms such as “dyspnea,” “orthopnea,” and “fatigue.” Indeed a practice of intentional splitting can keep a SAE off the product label. In addition to the use of SMQs, when available, bias can be controlled by DMCs adopting a rule that if an entire organ class has only 1% incidence, then only the organ class will be analyzed as a whole. If the organ class has 5% incidence, then the preferred term analysis can be undertaken. It should be understood that interpretation of the MedDRA table is not strictly a statistical issue.

Competing risks is a long-standing analytic issue for biostatisticians and should not be overlooked by DMCs. In a clinical trial, there may be low incidence of an adverse event in one treatment group only because patients have discontinued treatment due to toxicity, progression, or death. These events are the competing risks to adverse event observation, and their presence means this treatment group cannot necessarily be declared at low risk to this adverse event. The low incidence could be merely because patients in that group have not been in the trial long enough to experience this adverse event. This underscores the importance of always considering exposure in analyses and for the DMC to always get reports from the DAC of patient-years exposure in each treatment group. In the section entitled “Hypothesis Testing” above it was suggested that treatment group differences might be analyzed by the Poisson rate ratio or the Kaplan–Meier life table method. These methods take exposure into account and can avoid biased inference due to competing risks.

DMC DECISIONS

Types of DMC Decisions

When trialists think of DMC decisions, they invariably concentrate on trial termination due to an efficacy endpoint demonstrating sufficient superiority or futility at a planned interim analysis. We will certainly describe interim analysis decisions below but will also review decisions the DMC might make regarding safety other than trial termination. These would include writing a “Dear Investigator Letter” informing investigators of potential risk and recommending changes in the informed consent document. Decisions of the DMC are advisory to the sponsor. It is the sponsor who will make the final decision taking the DMC opinion and other factors into account.

Decision-Making Environment

It is important to note that at most of their closed session meetings, the DMC is making decisions on safety without the knowledge of efficacy. Efficacy knowledge comes only at the planned interim efficacy analyses. Schactman and Wittes^[29] contrast the difference in safety analysis at the end of the trial by the sponsor, then unmasked, and analyses provided by the DMC with limited resources and, perhaps, only early efficacy data. Physician members of DMCs will often claim that they will use predefined efficacy metrics to follow the protocol on interim analysis decisions, but they do not consider this of use to them in deciding if patients are benefitting. The metrics are part of the clinical trial construct but are not the way they evaluate patients in practice. For example, a visual acuity measure would not persuade an ophthalmologist that a patient has benefitted from therapy for age-related macular degeneration if the patient still complains he/she cannot read the morning crossword puzzle.

When a Safety Issue Arises

As has been said previously, DMC concerns about differential SAE incidence will most often not be a result of computing a *p*-value. The clinical implications for exposing further patients to this treatment and the public health concerns of marketing this product will be paramount. Actions such as writing the Dear Investigator Letter, modifying the informed consent, modifying protocol for dose, eligibility, and schedule all have their unmasking potential, and care must be made in how this information is provided to the sponsor. If the DMC recommends trial termination due to safety, this should be taken as the beginning of a dialog with the sponsor rather than an absolute decision. The sponsor and PV unit may have further relevant information about the SAEs or other options.

In the event of safety concern, the biostatistical DMC member might want to warn other members of the “bad news travels first” phenomenon whereby SAE reports must be submitted within a short time frame, often 48 h, due to regulations, but reports of patients who do not experience this SAE float in at a slower pace. This could give a distorted view of the safety risk. It is often prudent to wait until more data arrive in order to avoid a hasty irreversible decision.

Planned Interim Analyses Regarding Efficacy

Many confirmatory trial protocols will have a planned interim analysis at which point the trial can be terminated due to demonstrated superiority of experimental treatment to control or by futility. These terminations would be justified by ethical and efficiency reasons if continuing the trial would not be likely to lead to a positive outcome (futility) or if there is already considerable evidence of

experimental treatment superiority. These analyses require unmasking, and thus, administering this interim analysis is an important DMC responsibility.

A hypothesis will be tested at the interim analysis and there will be a Type I error associated with this test. The significance level required for this test will have to be strategically selected so that, if the trial continues, the overall Type I error will be close to the customary 0.05. The process of multiple testing of a hypothesis is called *alpha spending*. The interim analysis will take place at an intermediate point(s) in the trial. As the analysis will be done in groups, we call this type of trial *group sequential*. In practice, there are at most two interim analyses and a final analysis in the trial. Two closely related methods for alpha spending are those of O'Brien-Fleming^[30] and Lan-DeMets.^[31] As an example of alpha spending, if there were to be one interim analysis halfway through the trial, the significance level for determining superiority might be 0.003 and 0.048 at the end of the trial, allowing for an overall Type I error of 0.05. The smaller significance level at the earlier time point makes sense because we would want only an extreme treatment difference to indicate the ethical necessity for terminating the trial.

Futility testing is also performed at interim analyses. This analysis computes an assessment of how likely we are to reject the null hypothesis of no treatment difference at the end of the trial under several assumptions of “drift” or trajectory of future efficacy results. The method most often used by DMCs for futility analysis is *conditional power*. Just as the term implies, this method considers the data accumulated at interim as given and then looks at several drifts, e.g., null hypothesis prevails, alternative hypothesis prevails, or current efficacy level prevails, and the power for null hypothesis rejection under each. No alpha spending adjustment is needed for futility analysis because the assessment is spending Type II error not Type I. Futility analysis should always have the modifier *binding* or *non-binding*. A common criterion for termination due to low conditional power (CP) is $CP < 0.20$. If a futility analysis is binding, then the trial will terminate if the condition is met. If nonbinding, a dialog with the sponsor will commence. The sponsor might want to continue the trial in order to get approval in other countries or to gather more data to plan a future trial. A review of methods and rationale for futility analysis in clinical trials is given by Herson et al.^[32]

Another assessment often made at interim analysis is *sample size reestimation*. We will review that method in Section “Adaptive Designs.”

Herson^[11] provides a numerical example illustrating the interim analysis methods described previously for a hypothetical rheumatoid arthritis trial.

Final Meeting

When the trial goes to completion, there are several potential DMC responsibilities such as reviewing safety

data in a final manuscript, in the integrated summary of safety, or on the product label. In practice, these tasks are rare because they take place so long after trial completion when all concerned have moved on to other responsibilities.

Interim Analysis for Infant Pharma Sponsors

Infant Pharma sponsors are especially vulnerable to trial termination or even to protocol modification or Dear Investigator Letters. They must report these events to their investors and often remind their DMCs of the seriousness of negative interim analysis results. Nevertheless, DMCs not only realize that their responsibility is to patients but are also aware of making hasty decisions.

EMERGING ISSUES

The art and science of clinical trials is constantly changing, and DMCs must reconsider the existing practices and invent new practices in order to continue to protect patient safety. The issues to be discussed herein concern novel trial designs, new data collection methods, training of DMC members, and administrative challenges.

Adaptive Designs

Surely, the most popular of the new clinical trial designs are the so-called *adaptive designs*. Dragalin^[33] and Gallo and Krams^[34] have provided a good overview of the types of designs proposed. Adaptive designs seek to accelerate drug development by allowing for using data collected during the trial to change some aspects of the design without changing the overall Type I error of the trial. The DMC will administer the adaptive design process described in the protocol without unmasking the sponsor and, using their knowledge of the safety data, not allowing a change that would place patients at greater risk of adverse events. This responsibility represents a considerable challenge to DMCs, and the best practices are only now emerging.^[11,35]

If a trial has more than two treatment arms representing different doses or drugs, an adaptive design might call for dropping an arm at an interim analysis. Similarly, in a two-arm trial, an interim analysis might call for changing the randomization from 1:1 to, e.g., 2:1 based on interim results. These changes cannot go into effect immediately or automatically. The DMC must consider the safety consequences of these changes. The treatment groups that have already presented safety concerns to the DMC might be now enrolling more patients than originally planned as a result of the adaptation scheme. The DMC will need some “white space” to talk to the pharmacovigilance group about the advisability of this type of change.

Another type of adaptive design is *sample size reestimation* and *seamless transition* from Phase II to Phase III. The methods of sample size reestimation are

summarized by Chuang-Stein et al.^[36] The methods use protocol-defined algorithms to increase the sample size to preserve the power in the face of increased variability or varying efficacy in the control group. Similarly, if Phase II data pass a protocol-defined efficacy criterion, the trial may proceed to Phase III and begin enrolling additional clinical sites and patients. Here again the DMC must decide if there is a safety justification for this change.

A popular sample size reestimation strategy is the Cui-Hung-Wang (CHW) method.^[37] It must be understood that, unlike other sample size reestimation methods, CHW is reestimating the sample size to deliver the desired power to the effect size observed at interim. This effect size will be smaller than the one deemed clinically significant at the start of the trial. This brings up considerable regulatory and ethical issues. It is the role of the DMC biostatistician to explain to the clinical DMC members that they must consider if they were comfortable with the observed safety profile at the original effect size are they still comfortable with toxicity when the effect size is as observed at interim. The clinicians must also be reminded that this effect size is smaller than what was originally considered clinically significant. This will take some thought on the part of the DMC and require communication with the PV unit. Surprisingly, many CHW designs are employed where DMC members are unaware that the method implies a change in effect size.

Novel Designs in Oncology

The recent interest in precision medicine in cancer treatment has brought the *umbrella* and *basket* trial designs to actual protocols. These are master protocol designs where treatments rotate in and out of the protocol, and statistical methods either drop treatments for lack of efficacy or promote them to Phase III trials. Here DMCs will have to have rotating members because the protocols never close. Perhaps each time a treatment is promoted to Phase III one master protocol, DMC member can leave that DMC to chair a DMC for the new Phase III trial. Of course, the DMCs will still have their safety monitoring responsibilities and will have to be careful to differentiate between the various treatments rotating through the trial.

Biosimilar Designs

Biosimilars are follow-on drugs for branded biologics just like generics are follow-ons for chemical-based drugs.^[38] Due to the manufacturing of biologics, biosimilars cannot be precise copies of the branded biologic as generics are considered for the chemical-based branded product. Thus, full-scale bioequivalence trials will often be required for regulatory approval. DMCs will have to concentrate on adverse events observed in the two treatment groups. This will not always be straightforward. In a breast cancer bioequivalence trial for the biosimilar of trastuzumab, e.g., patients in both arms will also

receive taxanes, but some investigator sites might use docetaxel and some paclitaxel. DMC members will have to be knowledgeable of which adverse events are related to which drugs, and there will not always be unanimous agreement on the differentiation.

Centralized Risk-Based Monitoring

For many decades, data quality and protocol adherence clinical research associates monitored investigator sites as employees of the sponsor or a contractor. The monitoring was accomplished by making multiple visits to the sites. The FDA recently issued a guidance document, indicating that site monitoring could now be centralized, and statistical and graphical methods could replace routine site monitoring.^[39] Sophisticated software is becoming available to accomplish this type of monitoring.^[40] As a result, DMCs will be receiving data quality metrics by site. Thus, keeping track of data quality and recommending site improvements will be another important responsibility of DMCs.

Fraud Detection

Closely related to centralized risk-based monitoring is the topic of detection of fraud in clinical trials. The data coming from the sophisticated software used might, occasionally, detect the evidence of possible fraud in the data submitted. Indeed, Herson^[11,41] has proposed a *Fraud Recovery Plan* to be written by sponsors before the onset of a trial and to be administered by a DMC whenever the possibility of fraud appears.

Training of DMC Members

Various methods for training and certification of DMC members prior to service have been proposed—workshops at professional meetings, online courses, apprenticeships, and so on. None of these methods have gained traction because of the belief that people with the required clinical and statistical expertise will always be available to advise sponsors. It would still make sense to have a ready pool of people who have never served on a DMC and allocate them only to DMCs with experienced members. It is not uncommon for vacancies to occur on DMCs for trials that have already passed the interim analysis stage. Surely, in this case, people from the inexperienced professional pool could be assigned as replacements for these vacancies as a means of training for future trials.

Mergers and Licensing

It is not uncommon for a sponsor to merge or be acquired by another company while a clinical trial is in progress. When this happens, there may be uncertainty as to who is in charge at the sponsor, and indeed, several key

sponsor study team personnel may leave the company. DMC members must insist on doing their job during this transition and not surrender their responsibilities until the successor organization has found a suitable replacement. In most cases, the same DMC will continue to operate under the new ownership.

CONCLUSION

The art and science of clinical trials is constantly changing, and this article has attempted to illustrate the traditional and emerging responsibilities of DMCs. In the future, data on adverse events and patient compliance may be arriving in real time from patient-wearable technologies and/or sensors in the patient's home. DMC members may be provided access to sponsor clinical trial databases and statistical software so that they can continuously perform analyses of their own rather than rely only on the periodic structured data displays coming from the DAC. Much work must be done in postmarket safety, and the emerging surveillance technologies will help with that. However, our understanding of new treatments begins with the original efficacy and safety profile, and DMCs will always have a vital role in this process.

Herson^[11] provides extensive tables on the content of a DRP and on DMC responsibilities as well as numerous case studies from actual DMC–sponsor interactions on clinical trials.

Abstract

A diagnostic medical device is used alone or with other information to help assess a past, present, or future health condition of a subject. This entry provides general considerations for measurement validation and clinical validation of diagnostic devices from a statistical perspective. This entry also discusses issues with diagnostic device training and validation as well as decision analysis.

Keywords: Clinical performance; Analytical performance; ROC; Classification; Decision threshold; Diagnostic accuracy; Predictive value; Decision theory; Training and validation.

INTRODUCTION

A diagnostic medical device is an instrument, apparatus, implement, machine, contrivance, implant, in vitro reagent, or other similar or related article, including a component part or accessory that is recognized in the official National Formulary, the United States Pharmacopoeia, or any supplement to them, intended for use in the diagnosis of disease or other conditions.^[1]

Diagnostic medical devices provide results that can be used alone or with other information to help assess a patient's past, present, or future health condition of interest (also known as target condition). Diagnostic devices encompass in vitro and in vivo diagnostic devices. In vitro diagnostic (IVD) devices are intended for use in the collection, preparation, processing, and examination of a biological sample taken from the human body, such as blood tests for signs of infections. In vivo diagnostic devices are intended for use within a whole and living organism, which provides an anatomical measurement (e.g., bone density, brain volume, and retinal thickness) or a physiological measurement (e.g., heart rate, uterine contractions). Although the term diagnostic is often associated with assessing the presence or absence of a disease/condition at the time of testing, the term as used in this entry is much broader than that. Diagnostic devices can also provide results useful for predicting a future clinical event, outcome, or condition. Intended uses for diagnostic devices include:

- diagnosis of symptomatic subjects
- screening of asymptomatic subjects
- monitoring patient status over time continuously (e.g., monitoring heart rhythms) or intermittently (e.g., monitoring cardiac health by electrocardiogram)

- monitoring patient treatment response (e.g., in leukemia patients with minimum residual disease)
- predicting a future state of health or clinical outcome in diseased subjects (prognosis) or disease-free subjects (risk prediction), and
- identifying patients who are most likely to respond to a treatment (companion diagnostic device)

The validation of a new diagnostic device includes both measurement validation and clinical validation. Measurement validation involves characterization of various aspects associated with a device's ability to detect or measure qualitative or quantitative attributes (measurand). Clinical validation refers to characterization of a device's ability to demonstrate clinically meaningful results, e.g., diagnose and monitor the target condition (condition of interest), or to predict the onset of a future condition or a treatment response. It is important to validate the measurement performance of the device before conducting the clinical validation study. For example, if measurement validation indicates poor measuring ability, then the developer may need to consider modifying the device before conducting a clinical validation study. Clinical validation involves two types of studies—diagnostic clinical performance study and clinical outcome study.^[2] A diagnostic clinical performance study of a medical test generates evidence on diagnostic accuracy, e.g., characterized by sensitivity and specificity, diagnostic positive and negative likelihood ratio (PLR/NLR), or positive and negative predictive values (PPV/NPV) in an intended use population.^[2,3] The intended use describes the clinical purpose, type of test, measurand, on what it measures (e.g., specimen type), where it measures (e.g., anatomical location), operation setting (e.g., laboratory, home use), and the population(s)

the test is intended for. For example, a clinical performance study may be a study comparing the result from the device with the result from the clinical reference standard (also commonly referred as “gold standard”) that is used to assess subjects for the target condition of interest.^[3] In contrast, a clinical outcome study generates evidence on whether the incorporation of a diagnostic device improves clinical outcomes on subjects.^[2] In a clinical outcome study, the device result is used during a treatment or management intervention. A clinical outcome study might be a randomized trial where the intent is to assess the impact of test results on clinical outcome by comparing clinical outcomes in one group in which the test results are used against another group in which the test is not used at all. Device performance is assessed in part by the intervention’s effect on a subject’s outcome.^[2] For example, a clinical outcome study is used to evaluate an implantable wireless monitoring system designed to provide pulmonary artery pressure of patients with heart failure. The clinical validity is assessed by comparing the heart failure-related hospitalization rate between the treatment group of patients who were managed by device results and the control group of patients who were not managed by device results. Diagnostic devices produce quantitative, semiquantitative, or qualitative (binary, nominal) results.

This entry provides general considerations of measurement validation and clinical validation performed after the diagnostic device has been finalized (i.e., the design parameters and the cutoff(s) have been finalized and locked down). Additional topics discussed in the entry are benefit risk analysis, training, and validation.

MEASUREMENT VALIDATION

Measurement validation of a device output is the characterization of various aspects associated with a device’s ability to detect or measure a qualitative, semiquantitative, or quantitative attributes (e.g., measurand^[4]). Throughout this section, the emphasis is on estimating and validating the measuring capability of a device.

For IVD devices, measurement validation is typically referred to as analytical validation. A device’s measurement performance can be impacted by preanalytical, analytical, and postanalytical factors. Preanalytical factors include specimen collection (timing, aliquoting, pipetting, retrieval, processing, etc.) as well as handling and storage (time, temperature, humidity, volume, etc.). Postanalytical factors include data entry and calculations by laboratory staff, interpretation of the result, data transfer, and the method used to report the results (electronic, paper, or telephone), etc.

Measurement validation for IVD devices consists of a range of analytical studies, including, but not limited to, an assessment of measurement bias, measurement precision (repeatability, intermediate precision, and reproducibility),

limits of detection and quantitation, limit of blank, reference intervals, linearity, matrix effect, stability (of the device and the measurand), interferences, sample commutability, cross-hybridization, and carryover, etc. The types of measurement validation studies required for a diagnostic device may depend on its intended use. The definitions of the terminology in this section are provided in literatures.^[5–13]

Limit of detection is defined as the lowest amount of analyte in a sample that can be detected with (stated) probability.^[8] Determining the limit of detection can be different for a device utilizing polymerase chain reaction and other types of tests.^[8] Linearity is the ability (within a given range) to provide results that are directly proportional to the concentration (amount) of the analyte in the test sample.^[9] Linearity assessment is an important part of measurement validation study for devices with quantitative results; while it may not be applicable for devices with qualitative results. The other important aspects of measurement validation commonly assessed are measurement bias and precision.^[5–7] Measurement bias for quantitative tests is the difference between the expectation of test results and the true value. Assessment of measurement bias involves the comparison between the new test and a reference standard for the true value. In a method comparison study, regression method can be used to estimate bias at any point along the measuring interval.^[4] When an imperfect comparator subject to measurement error is used, then systematic difference between the new device and the comparator will be evaluated.

Measurement precision is the closeness of agreement between replicate measurements on the same or similar object (e.g., sample) under specified testing conditions. The specified testing conditions can be repeatability conditions, reproducibility conditions, or some other set of intermediate conditions. The variables that may impact the device’s precision are testing site, reagent lot, operator, instrument, day, run, replicate, etc. When the device results are interpreted by readers, it may be important to evaluate the reader-to-reader variability when possible. For example, for immunohistochemistry (IHC) test systems and diagnostic imaging devices, reader is required to obtain final results. For categorical or binary measurements, precision is typically assessed by a measure of agreement of test results among the replicates.

Both bias and precision can be constant or vary across the measuring interval (low to high) of the device. Therefore, it is important to evaluate the measurement performance of a device at medical decision points for non-qualitative devices and near the device cutoff for qualitative devices. The cutoff here is defined as the threshold at which a qualitative device differentiates a positive (or disease) from a negative (non-disease) outcome. Evaluation of measurement validation may depend on the intended use and the technological characteristics of the test.

For tests that measure and record anatomical or physiological characteristics in vivo (e.g., electrocardiogram, imaging), the concept of measurement validation is important but may be difficult to assess in practice due to practical logistics or ethical concerns. For these devices, measurement validation may include animal studies, sometimes called test–retest reliability or bench testing. Numerous consensus standards for the analytical evaluation of medical tests are available to assist laboratories and manufacturers to evaluate medical tests.^[5–15]

CLINICAL PERFORMANCE

Clinical validation of a diagnostic device is the process through which one examines and provides objective evidence to confirm that the test results are clinically meaningful in the intended use population of the device. The study design, performance measures, and hypothesis testing as well as the statistical analyses are usually based on the intended use of the device. For example, a device used for disease diagnosis is evaluated for its diagnostic accuracy (true positive and negative fractions). In the evaluation of a screening test, the true-negative fraction may be emphasized. The validation of a monitoring device involves repeated testing on a subject over a specified time period, with the relationship between the target condition and the temporal pattern of the test results being of primary interest.

A diagnostic device with qualitative results is designed to determine whether a target condition is present or absent in a subject from the intended use population. The results of a diagnostic device can be binary (e.g., diseased vs. non-diseased), or ordinal (e.g., scores on IHC stained slides 0/1+/2+/3+), or multicategorical (nominal, e.g., genotype A/C/T/G). Analyses developed for binary outcome variables can be generalized to multinomial distributions. This entry will only focus on diagnostic devices with binary outcome. The clinical performance evaluation involves assessment of agreement between the new device output and the underlying “clinical truth,” determined by a clinical reference standard (Gold standard). The output of the clinical reference standard, whether the condition is present or absent, needs to be independent of the output of the new device under evaluation.

For a binary-valued test with possible results $T = 0, 1$ denoting test negative (0) and test positive (1) results, test accuracy is commonly evaluated with measures of classification and prediction of the absence or presence of disease $D = 0, 1$.^[11] Measures of classification involve the conditional probabilities.

$$\tau_d = P(T = 1 | D = d) \quad (1)$$

A common pair of classification measures is the *true-positive fraction (sensitivity)* τ_1 and the *true-negative*

fraction (specificity) $1 - \tau_0$, which are respectively the proportion of disease positive subjects that test positive and disease negative subjects that test negative. In order for a test to be informative, the test performance needs to satisfy $\tau_1 > \tau_0$.

Another important pair of classification measures is the positive likelihood ratio (PLR) and NLR τ_1/τ_0 and $(1 - \tau_1)/(1 - \tau_0)$, respectively. For example, if $PLR = 2$, then a test positive result is twice as likely in a diseased subject than a non-diseased subject. If $NLR = 0.5$, then a test negative result is twice as likely in a non-diseased subject than a diseased subject.

Measures of prediction involve the conditional probabilities:

$$p_i = P(D = 1 | T = i) \quad (2)$$

A common pair of prediction measures is the positive predictive value (PPV) p_1 and the NPV $(1 - p_0)$. Predictive values can be of prime importance to subjects and to their attending physician who is making a management or treatment decision based on the test result. However, PPV and NPV depend on the pretest probability (prevalence) of disease p . If disease is rare, sometimes studies are enriched for subjects with disease, which distorts the observed prevalence, and thus invalidating PPV and NPV estimated from the enriched study.

Fundamental relationships between prediction measures PPV and NPV and classification measures PLR and NLR are:

$$\begin{aligned} PPV &= \frac{p}{\left\{ p + \frac{1-p}{PLR} \right\}} \\ NPV &= \frac{1-p}{\left\{ (1-p) + p * NLR \right\}} \end{aligned} \quad (3)$$

In particular, PPV and NPV are monotone functions of PLR and NLR, respectively. Thus, even in studies enriched for disease, PPV and NPV can be estimated for a range of prevalence using the above relation.

If a clinical reference standard is not available, the true status of the subject may not be known with certainty. Thus, sensitivity and specificity of the new device cannot be estimated. Instead, one may validate a new device by comparing the new device to an established comparator, and such a study could involve a performance based on the new device’s positive percent agreement (PPA) and negative percent agreement (NPA) with the comparator. The estimations of the PPA and NPA are exactly the same as those of the sensitivity and specificity except that the basis of comparison is defined by the comparator, which has its own bias and imprecision when being compared to the clinical truth if there is any.^[3]

A summary performance measure of diagnostic accuracy is the area (AUC) under the receiver operating characteristic

curve (ROC).^[14,16,17] A ROC plot is a graphical description of test performance representing the relationship between the true-positive fraction (sensitivity) and false-positive fraction (1-specificity) mapped to the complete spectrum of assay cutoffs. A ROC analysis can be used for determination of the optimal cutoff value of a test. It is also frequently seen in comparing two diagnostic devices with continuous or ordinal measurement. The AUC represents the average device performance in ranges of sensitivity/specificity, which may have limited clinical interpretability.

Some devices are designed to provide prognostic or risk prediction rather than to diagnose any specific clinical conditions. For example, detection of certain gene expressions may be linked to higher risk of recurrence in diagnosed and treated breast cancer patients.^[18] The true patient status in this case is defined by the clinical outcome observed through follow-up over a period of time. The risk prediction given by the diagnostic device at the baseline or through monitoring can be compared to the so-called truth observed at follow-up time.

Another type of diagnostic device produces quantitative/continuous output (interval scaled) value, e.g., a quantitative measurement [e.g., B-type natriuretic peptide (pg/mL) in whole blood or plasma as an aid in diagnosing severity of congestive heart failure], a ratio (e.g., D-dimer/fibrinogen ratio to diagnose pulmonary embolism), and a compositional result (e.g., percent of tumor-infiltrating immune cells exhibiting Programmed death-ligand 1 (PD-L1) expression, as detected in IHC staining, as a biomarker for likelihood of response to cancer immunotherapy). The validation studies for such devices usually focus on the quantitative relationship between the device output and clinical outcome. For instance, the efficacy of a medicine targeting patients with specific genetic mutations may be highly correlated with the gene expression scores reported by the medicine's companion diagnostic. In this case, the researchers may want to demonstrate the effectiveness of the diagnostic device using survival analysis. The connection between the patients' survival hazard and the device output can be established by fitting a Cox proportional hazards model to the collected time-to-event data with the gene expression scores as a major covariate. An alternative option is to model the occurrence of the event of interest (e.g., death of the patient) using a generalized linear model involving the gene expression scores. Various study designs and statistical modeling can be used to validate a quantitative device, depending on its intended use.

In contrast, some quantitative devices are aimed to measure quantity of a measurand, e.g., a blood glucose measurement or a red blood cell count obtained from a patient's capillary blood sample. In this case, an appropriate measurement validation study can constitute the clinical validation study by comparing the measurement to a reference method or any established comparator. The developer is expected to collect sufficient number of clinical samples/device measurements from subjects covering the claimed measuring

interval of the new device. Equivalence of the quantitative measurement between two devices is usually demonstrated using the agreement between the results reported by the new device and the reference/comparator device. Agreement can be assessed via a linear regression model allowing for measurement error in measurements from both devices.^[4] In addition, bias (difference) plots are good complements to the regression analyses.^[19] Guidelines and recommendations for study designs and data analyses used to validate quantitative diagnostics are available from many sources.^[4]

Often diagnostic devices involve human readers to make interpretation and assign a diagnosis, e.g., mammography for breast cancer, whole slide imaging for primary pathological diagnoses, etc. The setup of laboratory environment, readers' skills, and their operating scales are known to have large variability and can play an important role in the performance of the imaging devices.^[20,21] To evaluate the clinical performance of such devices, it is best to consider incorporating the readers' variability in addition to the case, system, and site variability in the study design and analysis. A study design often used in this area is the so-called multireader multicase (MRMC) study in which every reader reads all modalities (e.g., an investigational technology vs. the current practice) for every case. It is important for the reading schemes in MRMC studies (e.g., sequential or crossover design) to be aligned with the intended use of the device (e.g., adjunctive, concurrent use, or replacement). To avoid bias in the estimation of the device performance, the readers need to be properly blinded to any information related to the identity and reference diagnosis of the enrolled samples. Reading schemes involving multiple sessions, randomized reading orders, and washout periods of sufficient length can be helpful for removal of the memory effect and reading session effect.

The heterogeneity of the study populations is of concern. To evaluate whether the device performance is dependent on the patient profiles, the environment, and setup of the medical practice, it may be desirable to perform the validation studies at multiple geographic locations and enroll patients of different age, gender, and race to cover the complete spectrum of the intended use population. In case some of the covariates have significant effects on the device performance, one may choose to report the average device performance estimated from the pooled data together with the estimates stratified by any control factors of interest. Some alternative statistical methods such as the Cochran-Mantel-Haenszel test can also be used to evaluate the association of test result with disease status after adjustment for strata (categorical covariates) that may be correlated with both variables. Stratified analysis can be helpful in examining the device performance in various subgroups. Any multiple testing needs to be prespecified with appropriate allocation of alpha in order to control type I error.

The validation studies are considered successful if the performance metrics/end points can be shown to exceed prespecified acceptance criteria dictating that the study

results have clinical significance. The desired performance level varies with the intended use of the new device. A new device intended to replace an older technology may require evidence of non-inferiority or even superiority when they are both compared to the clinical reference standard. A particularly interesting example rises in the development of companion diagnostics such as the mutation tests for epidermal growth factor receptor (EGFR) exon 19 deletions and exon 20 (T790M) substitutions. These tests target the mutations known to have significant impact on the treatment effect of certain EGFR tyrosine kinase inhibitors on diagnosed non-small-cell lung cancer patients.^[22]

Studies evaluating the performance of diagnostic devices could result in missing data, in particular missing test results and/or the clinical reference standard. Reasons for missing data may include invalid or uninterpretable test results, insufficient or unevaluable specimen, lack of informed consent, lost follow-up, etc. Simply reporting the naive estimates of diagnostic performance only on subjects with complete data can be biased and misleading. The *intent-to-diagnose* (ITD) principle illustrates not to discard subjects with missing data from an analysis of diagnostic performance.^[23] ITD is analogous to the well-known intent-to-treat principle in therapeutic randomized trials to analyze patients as randomized to preserve the integrity of the randomization. Some diagnostic devices provide an indeterminate or equivocal result. While these results are not missing, they too are sometimes discarded from analysis, which can similarly bias diagnostic performance. Missing data can frequently be reduced if types of potential missing data can be identified at the planning stage and study procedures can be developed to prevent or obtain missing data. Missing data may not be rare even in a very well-designed study with strict compliance. Reporting the percentage and reasons of missingness provides relevant information for further investigation. When meaningful for analysis, multiple imputation of the missing data can be considered. When appropriate, robustness analyses using proper imputation techniques can be indispensable for the unbiased evaluation of the device performance.

DECISION THEORY FOR DIAGNOSTIC TESTS

To facilitate decision-making in the medical management of subjects, one or more thresholds or cutoffs in a continuous test result are often applied. For a single cutoff c , subjects can be defined as test positive or test negative based on the cutoff, $t = \phi(x) = I(x > c)$. Without loss of generality, we will denote the binary test result $t = \phi(x) = I(x > c)$. Test negative and positive results may indicate, respectively, likely absence or presence of disease.

An important question is how to set the cutoff to meet clinical objectives. Statistical decision theory can be used to select a cutoff that minimizes the expected loss associated with test classifications, according to a loss function.

Suppose the clinical “loss” incurred from a false-positive result relative to a false-negative test result is r and that true-positive and true-negative losses are 0. If $d = 0, 1$ indicates absence and presence of a disease with prevalence p , then the loss function is:

$$L(c, d) = t(1 - d)r + (1 - t)d \quad (4)$$

which has expectation:

$$E[L(c, d)] = \tau_0(c)(1 - p)r + (1 - \tau_1(c))p \quad (5)$$

where,

$$\tau_d(c) = \Pr(t = 1 | d) = \Pr(x > c | d) \quad (6)$$

i.e., $\tau_0(c)$ is the false-positive fraction ($1 - \text{specificity}$) and $\tau_1(c)$ is the true-positive fraction (sensitivity) of the test at threshold c . Considering the ROC plot of $(\tau_0(c), \tau_1(c)) = (s, \text{ROC}(s))$ for every cutoff c in x , expected loss may be reexpressed as:

$$E[L(s, d)] = s(1 - p)r + (1 - \text{ROC}(s))p \quad (7)$$

Setting to zero the derivative of expected loss with respect to false-positive fraction s , we find it is minimized when:

$$\frac{\partial \text{ROC}(s)}{\partial s} = \frac{r}{\theta} \quad (8)$$

where $\theta = p/(1 - p)$ is the pretest odds of disease.^[17] In words, the optimal cutoff in terms of minimizing expected loss corresponds to that point on the ROC plot at which the derivative (slope of tangent line) is r/θ . This theoretical result can be extremely useful not only in the development of an operating point (cutoff) for a test but also for comparing the operating points of two tests with the same intended use.

For a point on the ROC plot corresponding to cutoff c , the derivative is the diagnostic likelihood ratio $\tau'_1(c)/\tau'_0(c)$, where $\tau'_d(c) = \Pr(x = c | d)$. Thus, when deciding if disease is present or absent, the Bayes decision rule minimizing expected loss given test result x declares disease to be present if:

$$p_x/(1 - p_x) \geq r \quad (9)$$

or equivalently,

$$p_x \geq r/(1 + r) \quad (10)$$

where $p_x = \Pr(d = 1 | x)$ is known as the *risk score* or predictive value of x for disease.^[24] This Bayes rule holds in general when the risk score is a function of a vector of measurements x . The risk score may be used to set the optimal cutoff. It is appropriate even if based on a retrospective case-control study in which the prevalence is

incorrect because the risk score is a monotonic function of the likelihood ratio, which is independent of prevalence.^[24]

More generally, non-zero losses may also be assigned to true-positive and negative test results.^[24,25] For example, while a true positive correctly classifies a subject's disease status, it nonetheless may lead to an invasive medical procedure with attendant risks of adverse events.

Decision theory for diagnostic tests may be formulated equivalently with utilities rather than losses. For risk prediction, expected utility of the test relative to a perfect risk prediction may be plotted as a function of threshold in risk at which a patient is willing to be treated.^[26] Statistical decision theory appears to be underutilized in the development of diagnostic tests and the evaluation of their benefit–risk trade-off.

TRAINING AND VALIDATION

Diagnostic devices (tests) may involve a model or algorithm that separates patients into classes with or without the condition or into different grades based on relevant parameters. The reason for developing classifiers is to allow reliable classification of patients. A classification model is usually developed on one or more training data sets. However, it may not be sufficient to show that the model/algorithm predicts outcome in the data used to develop it. If a classifier is evaluated on the same data set(s) on which it was trained, its performance (e.g., diagnostic accuracy) can be vastly overstated, leading to the so-called resubstitution bias. The bias can be especially acute if the number of variables considered for inclusion into the model approaches or exceeds the training set sample size.^[25,27]

Generally, building and validating a classifier involve three steps. The first step is building the classifier. Then, it is fine-tuned to fit the device's intended use. Finally, it is validated on a different, independent data using subjects/specimens from the intended use population to assure that the study results can be generalized.

The training data set is the data on which the test or classifier is developed. Internal validation, which is sometimes done on all or part of the training data set, is used to fine-tune the model. External validation on a separate independent data set is generally referred to as testing. During the development of the classifier, one needs to be blinded to the test data. The classifier needs to be finalized or fixed, before one can look at the testing data set.

Quite often, issues arise with validating the classifiers. Some of the issues are: 1) assuming internal validation is external validation when it is part of training; 2) looking at the test data before the classifier is fixed; 3) using data that have been previously used to support a different/ modified classifier; and 4) using parts of the same data set to build and validate the classifier.

For internal validation, it is fairly common to use different parts of the same data set. Investigators may use one

part to build the classification model and the other part to validate (test) the model. They may use all the data to develop and validate the model (e.g., bootstrap method or k-fold cross validation). Both of them, however, are internal validation, and cannot substitute for external validation, which is generally done on an independent data set to which people developing the model are blinded until the model is fixed. Cross-validation estimates of performance, even if properly carried out, may not generalize out of the training data set. A reason is that the classifier may have been fitted to patient characteristics, specimen (or imaging) characteristics, and measurement errors (e.g., batch effects) that were peculiar to the training data set.

External (out-of-sample) validation refers to evaluating a “locked-down” classifier on a cohort of subjects that is completely independent of the training set(s). External validation mimics how the classifier will be used in practice, namely, to classify subjects. A well-designed and conducted external validation study provides estimates of classifier performance that are generalizable to the intended use population.

Gary Collins^[28] described this in a review of articles on multivariable prediction from 2010. They conclude that a vast majority of studies describing some form of external validation were poorly reported and state that this is consistent with other reviews of prediction models. They proposed an initiative, called Transparent Reporting of a multivariate model for Individual Prognosis Or Diagnosis (TRIPOD). These are essential guidelines for reporting, rather than developing and validating the model, but planning for appropriate reporting should also lead to an appropriate study design.

The TRIPOD initiative started by developing an extensive list of items based on a review of the literature that was reduced after a web-based survey and revised during a 3-day meeting in June 2011 in Oxford, United Kingdom, with methodologists, health-care professionals, and journal editors. The list consists of a checklist of 22 items, deemed essential for transparent reporting of prediction model studies.^[29]

Guidelines for classifier development and validation are available regarding best practices^[30] and reporting.^[29]

CONCLUSION

This entry discusses the evaluation of diagnostic devices, covering clinical and measurement validation, risk and benefit analysis, training, and validation. These general considerations are applicable to a variety of medical tests. This entry does not discuss other types of diagnostic device evaluation such as the clinical validation of companion diagnostic devices. For study design and analysis of companion diagnostic devices and precision medicine, the chapters on “companion diagnostic” and “precision medicine,” respectively, are referred.
